## I. Introduction.

### 1. The object of the marking experiments.

IN the Danish marking experiments with plaice the fish were as a rule liberated at the same spot where they were captured. In some cases, however, the fish have been transported shorter or longer distances before liberation. The aim of those experiments where the fish were liberated at the place of capture was in the main as follows:

- 1) To throw light upon the intensity of fishing.
- 2) To contribute to our knowledge with regard to the rate of growth of plaice on the various fishing grounds.
- 3) To yield information with regard to the natural migration of plaice.
- 4) To procure information as to the nationality of the vessels which catch the majority of the plaice on the various fishing grounds.
- 5) To elucidate what proportion of the marked fish are caught by trawling-vessels and what proportion by cutters and smaller vessels in the various areas.

The transplantation experiments have also to some degree enabled us to obtain information regarding the circumstances mentioned under 1—5. The main object of these experiments has been, however, to procure information as to the prospect of profitable transplantation on a large scale in the sea, the plaice being removed from grounds where they are crowded and increase in growth slowly to areas where they are scarce and increase rapidly.

### 2. The method of marking.

In the marking experiments Dr. PETERSEN's method has been used. Two bone-buttons have been attached to the fish by means of a silver-wire passed through the interspinous bones near the dorsal-fin, somewhat nearer the head than the tail. The bone-button on the eye-side is provided with a small depression wherein is placed a brass-disc provided with a number. The same method of marking is used in England, Belgium, Holland and Sweden, with some slight modifications. This method has on the whole proved to be practical, though not perfectly satisfactory in all respects. If the results of a marking experiment are to be called satisfactory we may make the following claims:

- a) The labels must be sufficiently large and distinct to be easily discovered by the fishermen or the people who later on manage the fish.

In this direction the Danish labels are quite good.

- b) The labels must be constructed and fixed in a way that does not much injure the fish.

The Danish method of marking may also in this respect be called satisfactory. When the buttons have not been squeezed too tight to the fish we very rarely observe a serious wound caused

by the labels. Another evidence that the marked fish are in good health we possess in the fact that they grow on an average with a similar rapidity to those not marked.

- c) The labels must be made of such a material and fixed on the fish in such a manner that they will last as long as the specimen lives.

In this respect we are still far from the ideal. We may at present be quite content if the labels remain on the fish for one year, so that we may get information as to what degree the fishery has affected the stock throughout the year. Experience has shown that the labels generally last at least for one year. After 1—2 years, however, the bone button on the blind side is generally corroded by the sea water, and no label is known to have lasted for more than  $2\frac{3}{4}$  years. But even if the label is rather durable the fish may lose it because it has not been sufficiently well fixed. It is sometimes noticed, especially in smaller specimens, that the silver wire which fixes the label has caused a longitudinal wound between the interspinous bones so that the label has moved out against the edge of the body. Several labels are probably lost in this way before one year has passed.

### 3. The condition of the marked fish when set free.

It is naturally of the utmost importance that the marked fish should be liberated in a perfectly living condition. This has generally been the case in the Danish marking experiments; but in spite of the care we have taken on this point, it seems that we have not always been careful enough. Thus it has been ascertained that a few of the marked plaice have been taken dead from the sea-bottom shortly after liberation. I therefore suppose GARSTANG to be right when he says that "it is quite possible that a certain number of fishes receive injuries during the act of trawling which are incapable of detection at the time when the fish are marked and yet may be severe enough to cause a certain mortality among the fish used in the experiments".

While it is quite exceptional that marked plaice have been liberated in the ordinary marking experiments when not capable of living, we have reason to suppose that the condition of the plaice which were liberated in the Danish transplantation experiments in spring of 1904, has not always been as satisfactory as it ought to have been. The slight percentage which has been recovered of these transplanted fish points in this direction. The weather was very unfavourable during several of these experiments, and it became in several cases evident that the plaice were weakened during the transplantation.

It seems as if I have in some cases overestimated the vitality of the plaice. I have thought that, even if a plaice has become a little weak during the transport, it will soon recover when placed in the sea. Experience seems to show that such has not always been the case.

The plaice liberated in the marking experiments were as a rule caught by the "Thor" with a 50 feet ottertrawl in hauls lasting from ca.  $1\frac{1}{2}$ —2 hours. In some cases they were captured in the snurrevaad by Danish cutters.

### 4. The areas where the marked fish have been set free.

The Danish marking experiments with plaice in 1903—1906 were made in the following areas:

- 1) In the North Sea N. of  $55^{\circ}0'N.$  lat. and E. of  $6^{\circ}0'E.$  long.
- 2) In the southern Skagerak on the Danish land-ground at depths between 0 and 50 meters.
- 3) In the Kattegat west of a line drawn from Elsinore over Little Middelgrund to  $58^{\circ}0'N.$  lat. and  $11^{\circ}0'E.$  long.

In that part of the North Sea where the marking experiments were made we may distinguish between two areas: The Horns Reef area and the Hanstholm-Søndervig area. The Horns Reef area comprises the grounds around the Horns Reef and the so called "Horns Reef Outer Grounds", lying

between 55°0' and 56°0' N. lat. and E. of 6°0' E. long. The Hanstholm-Søndervig area comprises the coastal grounds off the west coast of Jutland between 56°0' and 57°10' N. lat. and E. of 6°0' E. long.

As limits between the different waters are here considered:

Line: Hanstholm—Lindesnæs between the North Sea and the Skagerak.

» Skagen—Paternoster » the Skagerak and the Kattegat.

» Gníben—Hasenørre » the Kattegat and the Belt Sea.

» Elsinore—Helsingborg » the Kattegat and the Sound.

The submarine ridge: Dragør—Saltholm—Linhamn between the Sound and true Baltic.

» Gedser—Darsserort » the Belt Sea and true Baltic.

### 5. The records of the fishermen and the registration of the data etc.

The Danish fishermen and fishmongers have on the whole shown a praiseworthy readiness in sending information regarding recovered marked fish, in spite of the fact that the reward offered has been rather low (1 Kr.). It has sometimes occurred that we have by chance obtained information that marked fish had been recovered, though no information was sent to our office. Such occurrences are however rare exceptions. More than 90% of the marked fish are in several of our marking experiments registered as recovered, a fact which shows the fishermen's and the fishmongers' readiness in sending accounts of the recaptures.

At the most important fishing ports we have had local assistance from people, who received the fish from the fishermen, measured them and paid the reward. In Frederikshavn we have thus been assisted by Mr. CLOOS LORENTZEN, in Skagen by Mr. L. HOLST, and in Esbjerg by the harbour master Lieutenant JENSEN.

For information regarding Danish marked fish recovered by foreign fishermen we are indebted to the authorities in the respective countries, who have had these matters in their charge.

### 6. The shrinkage of fish after death before remeasurement.

The fish recovered during the same month in which they were liberated measure on an average ca. 0·5 cm. less at recovery than at liberation (Compare Contributions I, p. 23). This is naturally owing to shrinkage after death before the remeasurement takes place. Several specimens measure up to 2 cm. less on remeasurement after recovery than at liberation. In accordance with the experience gained and with the results of several experiments which we have undertaken in order to substantiate the amount of shrinkage when the fish were dried I have summed up the following as giving approximately the real size of the fish at recovery:

If stated: "fish fresh" or "fish living": 0 cm. is added.

If nothing stated about condition of fish: 0·5 » »

If stated: "tail dry": 0·5 » »

If stated: "fish rotten": 1·0 » »

If stated: "fish dry" or "fish salted": 1·0 » »

This implies that on an average 0·5 cm. has been added to the observed length of the recaptured fish by the calculation of the growth.

The fish has in each case been calculated to be at least as large on recovery as at liberation.

Among the experiments which we have carried out to test how much the plaice will shrink when dried up, the following may be recorded.

On October 2., 1906, 11. a. m., 30 living plaice of a length of 21—36 cm. were laid out on the deck of the "Thor".

They were left on the deck for 24 hours in fine weather; then they were remeasured and the shrinkage amounted to 4—9 mm., on an average to 5·6 mm. The majority of the marked plaice landed in Esbjerg are in a similar state.

The 30 specimens were now utterly dried up and on October 12. they were in such a state that they properly might be termed as "Fish dry" or "Fish somewhat dry". The shrinkage now amounted to between 7 and 13 mm., on an average to 9·6 mm.

The shrinkage of each of the individuals was as follows:

Original length 2. — 10. — 06.	Shrinkage until 3. — 10. — 06.	Shrinkage until 12. — 10. — 06.	Original length 2. — 10. — 06.	Shrinkage until 3. — 10. — 06.	Shrinkage until 12. — 10. — 06.
213 mm.	6 mm.	9 mm.	257 mm.	6 mm.	11 mm.
218 »	6 »	8 »	260 »	6 »	8 »
226 »	6 »	10 »	265 »	9 »	12 »
228 »	6 »	9 »	268 »	7 »	11 »
234 »	8 »	11 »	269 »	6 »	13 »
235 »	4 »	9 »	270 »	5 »	9 »
235 »	4 »	9 »	272 »	6 »	9 »
239 »	8 »	13 »	274 »	4 »	8 »
241 »	4 »	9 »	276 »	5 »	10 »
241 »	5 »	11 »	284 »	4 »	9 »
244 »	4 »	8 »	287 »	6 »	10 »
250 »	4 »	9 »	315 »	4 »	10 »
252 »	5 »	8 »	316 »	6 »	10 »
254 »	5 »	7 »	317 »	5 »	9 »
256 »	6 »	10 »	364 »	9 »	10 »

On salting and drying 9 plaice of a length of 22—28 cm. we found a shrinkage between 7 and 12 mm., on an average 9 mm. in the lapse of 4 weeks. The fish were at that time not quite dry.

#### 7. Particulars concerning the Tables, Figures and Plates.

In the Tables stating the particulars of liberation and recovery of the marked plaice S. S. and S. T. mean steam-ship or steam trawler, S. B. = Decked or sailing boats (cutters), "Fishingb." means small sailing boats or small motor boats (below 10 tons brutto). The tables include recoveries up to the end of September, 1906.

The charts illustrating the marking experiments have been drawn by Mr. SIMONSEN.

On all the charts the head of the arrow indicates the position of recapture. The letters beside the arrow heads represent the nationality of the vessels which recaptured the plaice, B. meaning Belgium, Da. = Denmark, E. = England, H. = Holland, G. = Germany, S. = Sweden. The Arabic numerals at the arrow-heads indicate the number of months between liberation and recapture, 0 meaning: recaptured in the same month as liberated, 1 meaning: recaptured 1 month after liberation and so on.

The Figures 1 to 9 represent the plaice which were recaptured until June 30., 1905. The Figure 10 and Pl. I to VI represent plaice recaptured until Septbr. 30., 1906.

The depth-lines are the same on the Figures as on the Plates.

## II. Detailed account of the Danish marking and transplantation experiments with plaice in the North Sea, the Skagerak and the Kattegat in the years 1903—1906.

### A. The ordinary marking experiments in 1903. Supplementary records.

In April of 1903, 1220 marked plaice were liberated from the investigation-steamer "Thor" off the west-coast of Jutland in the shore belt between 8 and 50 meters depth. At the end of 2 months and a half after the liberation 304 of the marked specimens or ca. 25% were already recovered. In the first year after liberation 361 specimens or 29.6% were recovered, in the second year 32 specimens or 2.6%, and in the third year 4 specimens or 0.3%. The last specimen recovered was caught on July 28th, 1905. Until September 30th, 1906, the total recatch amounted to 397 or 32.5%.

In "Contributions to the Biology of the Plaice I" I have dealt with the marking experiments of 1903 and given particulars with regard to the specimens recovered up to the end of June, 1904. The following supplementary records comprise one specimen recaptured in April of 1904 and 8 specimens recaptured between July 7th of 1904 and July 28th of 1905. These specimens are of special interest on account of the proportionally long time which has passed between the liberation and the recovery.

Table 1. Supplementary list of Recoveries from the Danish marking experiments with plaice in April, 1903.

Marking experiment No. 7 1903 Jammer Bay. April 17, 1903	1904 July 7	1003	NNE of Hanstholm. 24 miles f. shore. 22 fms.	57°30' 8°44'	Danish S. B.	XV	♂	20	35	
Marking experiment No. 16 1903 Off Torup. April 23, 1903	1904 July 17	1166	Monkey Bank	56°30' 6°30'	German S.T.	XV	♀	35	41	

It will be seen from Table 1 that 5 specimens liberated in the Horns Reef area have grown after ca. 2 years respectively 8, 10, 11, 13 and 17 cm. One specimen liberated in Jammer Bay in the Skagerak increased in size during 15 months from 20—35 cm.

Fig. 1 represents the position of recapture of the above mentioned plaice which were liberated in April, 1903, and recovered between 15 and 26 months after the liberation. It will be noticed that all the specimens save one were recovered in deeper water than that in which they were liberated. This corresponds with the general tendency of the plaice to leave the shallow water as it increases in size. At the end of 25 and 26 months 2 specimens were recovered on the Horns Reef grounds where

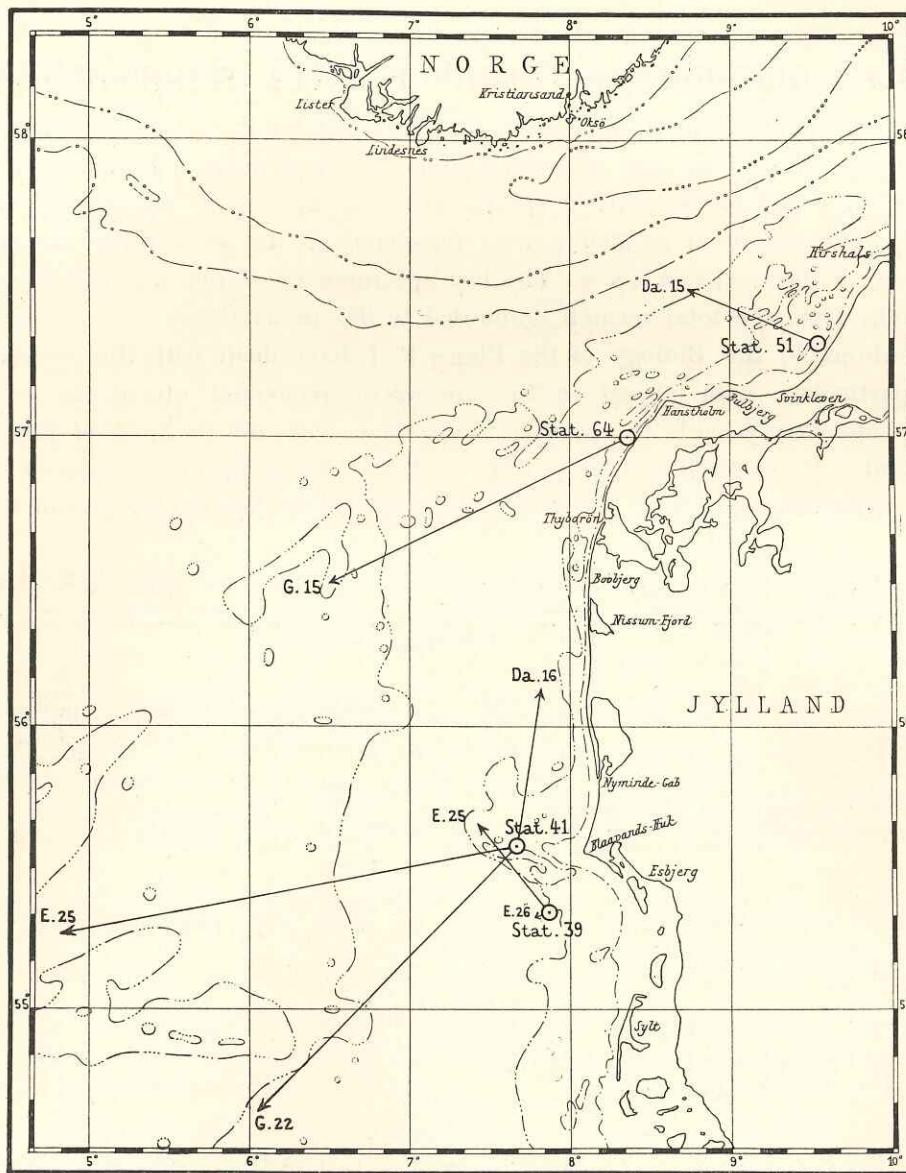

Fig. 1. Marking experiments with plaice. April 1903. Supplementary chart.

they were liberated originally. How far these plaice have been wandering to and fro from shallow to deeper water during the 2 years can naturally not be ascertained.

### B. The ordinary marking experiments in the spring of 1904.

In the ordinary Danish marking experiments in February and March, 1904, 210 specimens were liberated near the Horns Reef and 90 specimens in the north-western Kattegat.

A detailed account of the experiments is represented on the Tables 5 and 6. The list of recap-

tures of the marked fish is here entered up to the end of September, 1906 and thus comprises a space of ca.  $2\frac{1}{2}$  years.

Of the 210 specimens liberated at Horns Reef in February, 76 specimens or ca. 36·2% were recovered by the end of one year. During the second year 10 specimens or ca. 5% were recovered. The total recaptures until September 30th of 1906 amounted to 86 specimens or 41·0%. 159 of the specimens measured at liberation 19—24 cm. and 51 specimens measured 25—31 cm. In one year 39 specimens or 24·5% were recovered of the first group and 37 specimens or 72·5% of the latter group.

The growth of the specimens liberated at Horns Reef is represented on Table 2. It will be seen that the increase here during the summer amounted to ca. 6 cm. for specimens of a total length of 20—30 cm. and that apparently no increase has taken place during the winter months of 1904—1905.

Marked plaice were also liberated by Germany in the Horns Reef area in the spring of 1904. 264 specimens were thus liberated W. and S.W. of Horns Reef at 23—30 meters depth. During the first year after liberation 86 of these specimens or 32·6% were recaptured. As shown on Table 3 the average increase was 3·5 cm. for 4 specimens of 28—31 cm. which were recaptured in July and August 1905, while the average increase was 5 cm. for 10 specimens of 20—27 cm., which were recaptured during the same months in the Danish marking experiments.

Of the 90 specimens liberated in the marking experiments in the northern Kattegat 76 specimens or 84·4% were recovered during one year. In the following year only one specimen was recaptured. Until September 30th of 1906 the total recaptures amounted to 77 specimens or 85·6%.

Of the marked specimens 35 measured at liberation 21—24 cm. and 55 25—32 cm. In the course of one year 30 specimens or 85·7% were recaptured of the first group and 46 specimens or 83·6% of the last group.

A survey over the growth of the specimens liberated in the northern Kattegat is represented on Table 4. The increase during the summer seems to be ca. 5—7 cm. for specimens of an average length of 22—25 cm.

A further account of the results of the marking experiments in spring, 1904 will be found in Chap. III: "Discussion of the Results of the Danish marking experiments with Plaice in the years 1903—1906".

the circles are the places of liberation.

### C. The transplantation experiments with plaice in 1904.

In spring, 1904, transplantation experiments with 1700 plaice of a length from 18 to 32 cm. were made by the "Thor" in the waters surrounding Denmark. The specimens were marked in the usual way with two bone buttons and a brass disc.

Most of the plaice were captured on the rich rearing grounds at Horns Reef and were transplanted partly into the Graadeep inshore waters, partly into deeper water in the Horns Reef area, and partly into the Skagerak. A smaller number, 60 specimens, were transplanted in the Kattegat from the Aalbæk Bay to Trindelen.

The plaice transported over shorter distances (less than 12 miles) were kept separately on the "Thor's" deck without any supply of sea-water. Those transported over greater distances were placed in wooden tanks in which sea-water was kept in circulation by means of the ship's pump and hose.

A detailed account of the experiments will be found in the Tables 10 and 11.

#### 1. The transplantation from the Horns Reef Grounds to the Graadeep inshore waters (the experiments No. 1, 8 and 9, Fig. 2).

In the experiments No. 1, 8 and 9 in February of 1904, 140 plaice were transplanted from the waters west of Graadeep to the Graadeep inshore waters, a distance of 7—12 miles. The black spot on Fig. 2 indicates the place where the specimens were caught.

The intention with these experiments was to elucidate if the fish would remain in the inshore waters during the summer till the autumn fishing took place, or if they would migrate to offshore grounds before that time.

The experiments have proved that the fish quickly began to migrate towards the offshore grounds. The tendency to migrate outward was so strong that not a single one of the transplanted fish was recovered in the inshore waters during the intense autumn fishing; thus it must be supposed that practically all disappeared from the inshore waters in the course of the spring and summer.

Of the transplanted 140 specimens 31 or 22.1% were recaptured within one year. Until Septbr. 30th of 1906 the total recaptures amounted to 36 specimens or 25.7%. As more than 40% of the liberated specimens were on an average recaptured in the ordinary marking experiments in the Horns Reef area in the course of one year, these transplantations thus show a considerably lower percentage of recaptures. Still it may hardly be supposed that the fish were injured during the transportation.

On Fig. 2 the places of recapture of the liberated specimens have been put down. Several specimens have been put down. Several specimens have migrated far from the place of liberation. One which was recovered in the Kattegat 12 months after liberation had moved more than 200 miles from the place of liberation.

The Table 7 p. 15 shows the increase in growth of the transplanted specimens. It may be noticed that the increase in size in the course of one year is ca. 6 cm. or about the same as has been noticed by the non-transplanted specimens in the Horns Reef area (compare Table 2 p. 9).

## 2. The transplantation from the Horns Reef coastal-grounds to the Horns Reef off-shore grounds. (Experiments 2, 3, 4, 5, 6 and 7.)

Fig. 2 and 3.)

In the experiments No. 2, 3, 4, 5, 6 and 7, 900 plaice were transplanted from the waters W. of Graadeep at  $55^{\circ}27' N.$   $8^{\circ}41/2' E.$  to deeper water in the Horns Reef area. Fig. 2 and 3 represent the places of liberation.

The intention with these experiments was to investigate

1) if the increase in growth of the transplanted specimens was considerably greater than that of the specimens which were marked and liberated in more shallow water,

2) if a considerable percentage of the transplanted specimens would be recaptured.

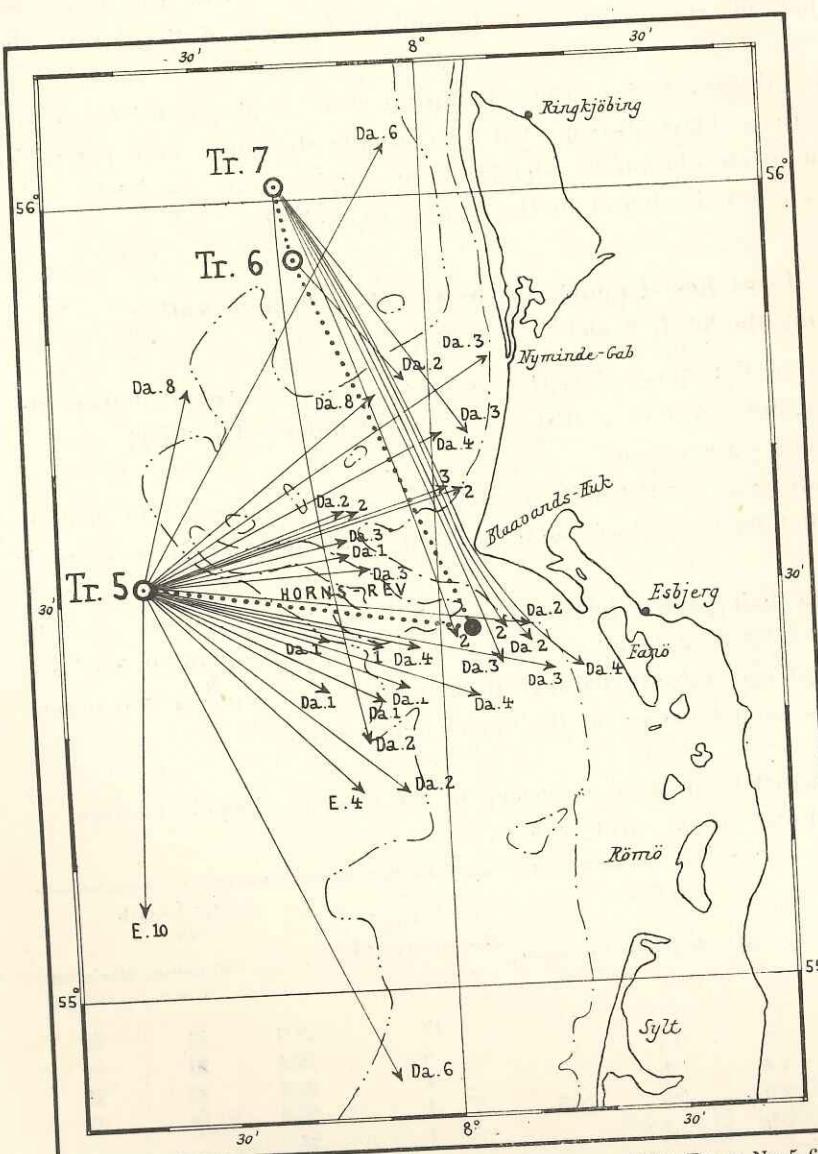

The experiments showed that only a

Fig. 3. Transplantation experiments with plaice. February, 1904. Exper. No. 5, 6, 7.  
The dark spot is the place of capture, the circles are the places of liberation.

very slight percentage of the transplanted fish, scarcely 5%, was recovered in the course of one year, also that these specimens did not increase perceptibly quicker in size than those which were marked and liberated in the coastal waters.

The main reason why only such a slight percentage was recaptured may probably be looked for in the fact that many specimens had been weakened during the transportation.

The specimens liberated in the 5<sup>th</sup> experiment 3 miles S. of the Horns Reef lightship at a depth of 31 m. had naturally suffered least, being transported over the shortest distance. In this experiment 13.5% of the liberated specimens were recaptured during one year.

When Fig. 3 seems to indicate that the transplanted specimens have shown a marked tendency to return to the Horns Reef Grounds, this is essentially due to the circumstance that a much more intense plaice-fishery is carried on here than on the off-shore grounds. The specimens migrating in a western direction have had a far greater chance of avoiding recapture than those moving in an eastern or south-eastern direction towards the Horns Reef Grounds. It is, however, a remarkable fact that not a single specimen is known to have migrated in a western direction towards greater depths.

The growth of the transplanted specimens is represented on Table 8. It will be noticed that the increase during one year is ca. 6 cm. which is about the same as in the not-transplanted specimens, which were liberated in more shallow water (compare Table 2 p. 9).

### 3. The Transplantation from the Horns Reef Grounds to the Skagerak. March 1st, 1904. (Transplantation experiment No. 10, 1904. Fig. 4.)

In the transplantation experiment No. 10, which took place on March 1st of 1904, 600 plaice were transplanted from Graadeep to the Jammer Bay in the Skagerak. The intention with this experiment was to obtain information as to whether the specimens transplanted from the Horns Reef area into the Skagerak would increase in size with a considerably greater rapidity than those remaining at the Horns Reef, also if a similar percentage would be recaptured of these transplanted specimens as of those caught, marked and liberated in the Skagerak.

The marking experiments in 1903 showed that the plaice in the Skagerak increased twice as much in size as did the plaice at the Horns Reef, a fact which naturally gave rise to the supposition that it would be of great importance from an economical point of view to undertake on a large scale the transplantation of young plaice from the Horns Reef to the Skagerak. (See Contributions to the Biology of the Plaice I p. 22—23).

The experiments carried on in 1904 have given the results, that only an exceedingly small percentage of the liberated specimens were recovered, and that these recovered specimens certainly increased with nearly twice the rapidity of the marked plaice at the Horns Reef in 1903, but not with a much greater rapidity than the marked plaice at Horns Reef in 1904.

Of the 600 transplanted plaice only 42 specimens or 7·0% were recovered within one year after liberation, and up to Septbr. 30th of 1906 the total recaptures did not comprise more than 45 specimens or 7·5%. If we compare how many specimens were recaptured in the ordinary marking experiments undertaken on the same areas where the transplanted specimens were liberated, it will be seen that the

small percentage of specimens recovered in the transplantation experiments cannot be due to a small intensity of fishing. It must evidently be ascribed to other causes.

Of the specimens liberated in the ordinary marking experiments in the Skagerak in April of 1903 and March of 1905 in the same area and at the same depth where the transplanted specimens from the Horns Reef were liberated in 1904, the following percentage was recaptured in the course of one year:

in the experiments in 1903: 53·1% (32 liberated 17 recovered)

» » » 1905: 47·8% (575 » 275 » )

Two reasons might be suggested *a priori* to account for the fact that only a very small percentage was recovered in the transplantation experiment. In the first instance we might suppose that the plaice were injured during the transportation and when liberated less able to live than in the ordinary marking experiments. Secondly it might be supposed that the changed conditions of life into which the plaice were transferred might be unfavourable and cause a migration from the place of liberation and eventually to grounds where the fishery was less intense. Probably both these factors have been of consequence, but in my opinion we shall have to look for the main reason for the small percentage of specimens recovered in the circumstance that the plaice became weakened during the transportation.

During the voyage from Graadeep to Skagerak the weather became gradually rougher and on reaching the Skagerak we met with a north easterly gale.

It was quite evident that the plaice had become weakened during the transportation. The strong movement caused by the high sea affected them seriously. They were repeatedly thrown about in the tank and many specimens showed signs of exhaustion. Several specimens died before we reached the place of liberation. My co-workers and helpers (among whom I may mention the sailing master Captain JØRGENSEN, an experienced master of trawlers, and Mr. TARBENSEN, an experienced fisherman from Esbjerg) as well as I myself thought at the time that the specimens which we marked and liberated were capable of living, but considering now how small the percentage is that has been recovered, I feel quite convinced that we must have overrated their vitality. When the plaice are beforehand somewhat weakened they are probably much affected by the irritation caused by the marking and later on by the attached label itself. At present definite specimens are also to hand of marked plaice which have been fished dead from the sea-bottom shortly after liberation. Though these examples do not originate from the transplantation experiments they are still of great interest, proving that plaice marked by experienced people, who believed them to be perfectly well and strong on liberation, have still suffered so much injury by the capture or the process of marking that they have died shortly after.

These examples are as follows:

1) Plaice marked Da. 220 liberated S. of Horns Reef on April 10th, 1903. Male of length 20 cm. Recaptured by an English steam-trawler on April 14th, 1903. GARSTANG records: "Fish not received, but the fisherman says the fish was dead and rotten when caught".

2 and 3) Plaice marked Da. 05, 1386, and Da. 05, 1420 liberated in Aalbæk Bay in North-West Kattegat on March 29th, 1905. Female of length 27 cm., and Male of length 22 cm. Retaken by a Danish cutter on April 5th, 1905. The fisherman said that they were dead and rotten when caught ("døde og bedærvede ved Fangsten"). Mr. LORENTZEN in Frederikshavn, who measured the fish shortly after they were caught, confirmed this statement.

It should be noted that two of the above mentioned plaice were relatively small specimens of 20 and 22 cm. length.

Even if the main reason, why such a proportionately small number of the specimens transplanted into the Skagerak from Horns Reef was recovered, is to be looked for in the fact that the plaice had become injured during the transportation and were partly moribund when set free, there is as said before a possibility that another concurrent cause of the slight number of recaptures may be sought for in the

fact that numbers of liberated specimens have quickly migrated away from the place of liberation and that some arrived at grounds subjected to less intense fishing. It appears, namely, as will be seen from the survey below, that a relatively large percentage of the recovered specimens had left the Skagerak before recapture (see Fig. 4).

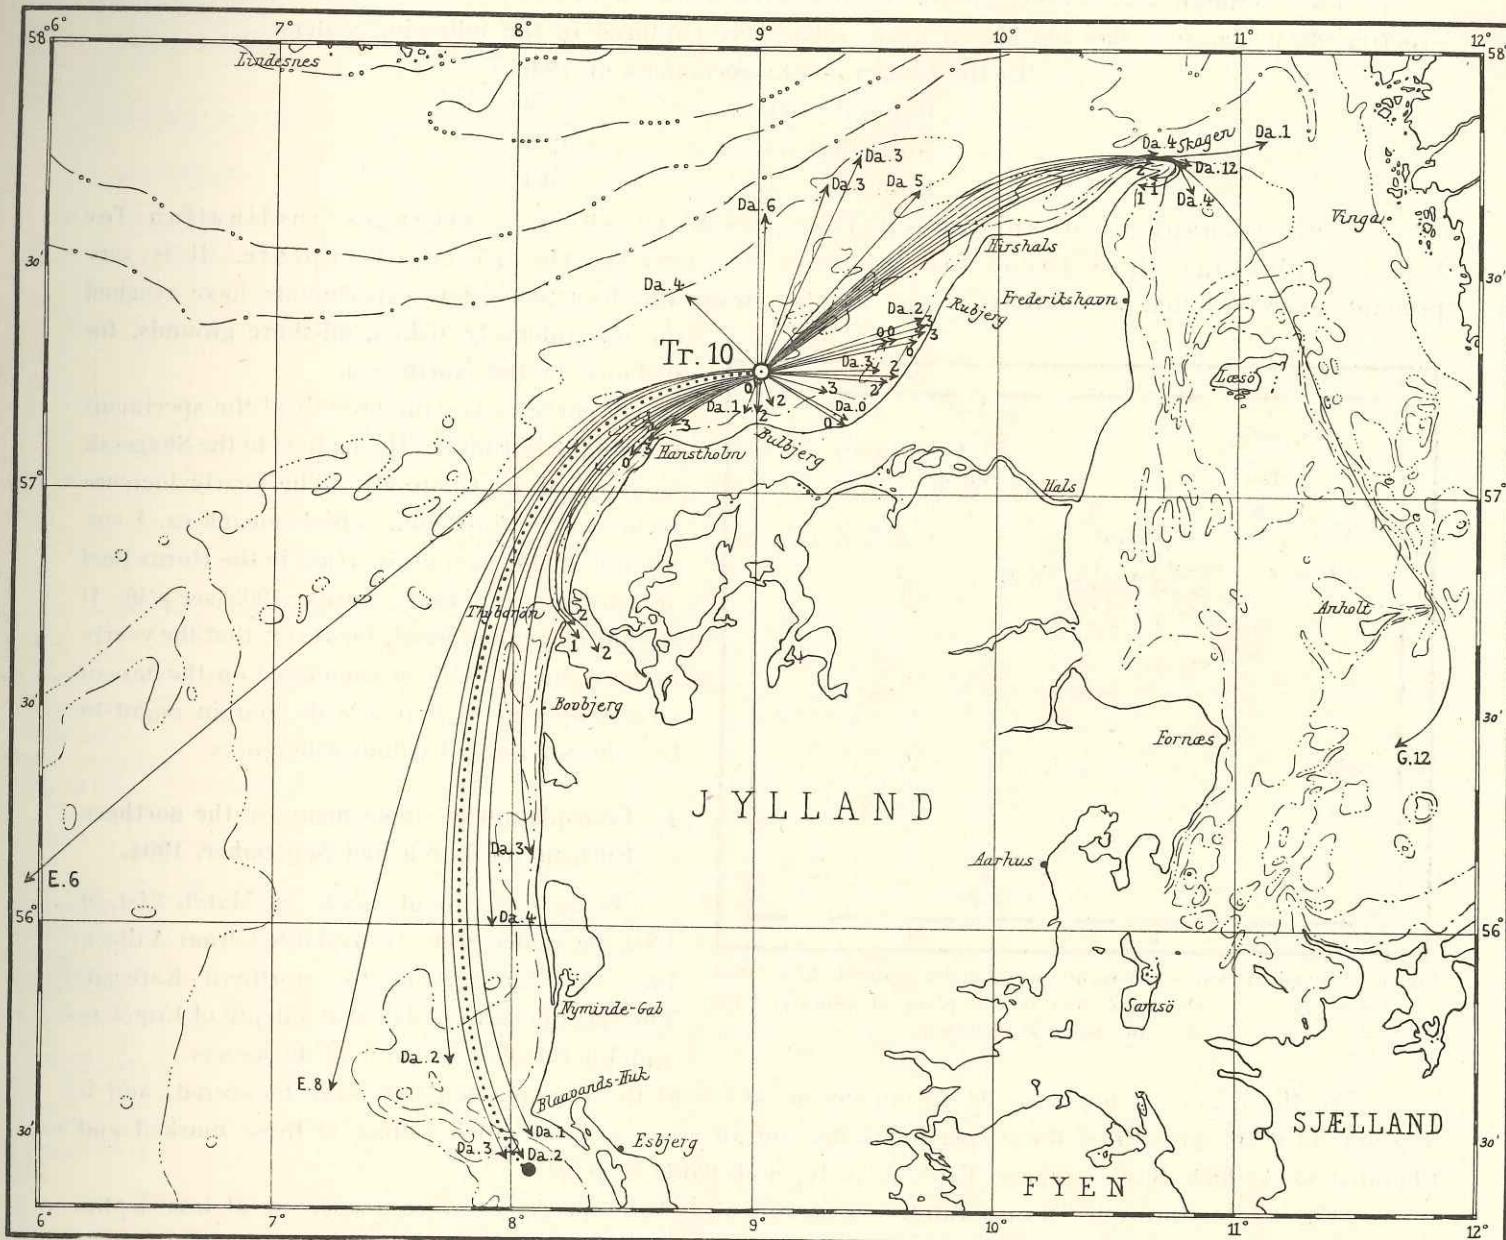

Fig. 4. Transplantation experiments with plaice. March 1st, 1904. Exper. No. 10. The dark spot indicates place of capture, the circle is the place of liberation.

The 45 specimens which were recovered before Septbr. 30th of 1906 from the transplantation experiment in Jammer Bay in the Skagerak on March 1st of 1904, were captured in the following waters:

- a) In the Skagerak 26 specimens or 57.8%
- b) » » Kattegat 5 » » 11.1%
- c) » » North Sea 11 » » 24.4%
- d) » » Limfjord 3 » » 6.7%

The 18 specimens, which were recovered before Septbr. 30th of 1905 in the ordinary marking experiments in Jammer Bay N.E. of Bulbjerg in April, 1903, were caught at the following places:

In the Skagerak 12 specimens or 66·7 %

» » North Sea 6 » 33·3 %

Two hundred and seventy specimens recovered before Septbr. 30th, 1906, in the ordinary marking experiments in Jammer Bay on March 22nd, 1905, were captured in the following waters:

In the Skagerak 215 specimens or 79·6 %

» » Kattegat 21 » 7·8 %

» » North Sea 33 » 12·2 %

» » Limfjord 1 » 0·4 %

The transplanted specimens thus seem to show a stronger inclination for long wanderings than those marked and set free at the place of capture. It is very probable therefore that a relatively large number from the transplantation experiments have reached the less intensely fished, off-shore grounds, for instance in the North Sea.

A survey over the growth of the specimens transplanted from the Horns Reef to the Skagerak is supplied in Chap. III. The yearly increase seems to be 7–8 cm., which means ca. 1 cm. more than the average increase in the Horns Reef area from spring, 1904—spring, 1905 (see p. 9). It should be remembered, however, that the yearly increase here has been calculated on the base of so few specimens that a wide margin ought to be allowed for individual differences.

#### 4. Transplantation experiments in the northern Kattegat in March and September, 1904.

In an experiment, made on March 21st of 1904, 60 plaice were transplanted from Aalbæk Bay to Trindelen in the northern Kattegat. The specimens were fished at a depth of 15 meters and liberated at a depth of 40 meters.

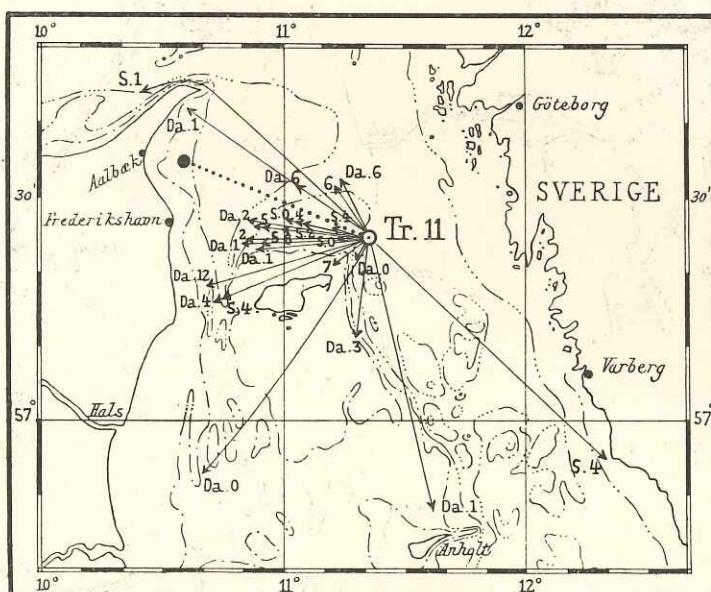

Fig. 5. Transplantation experiments with plaice. March 21st, 1904. Experiment No. 11. The dark spot is the place of capture. The circle is the place of liberation.

In the course of one year 34 specimens or 56·7 % of the transplanted fish were recovered, and it appears as if the growth of these specimens has on an average been quicker than of those marked and liberated in Aalbæk Bay (compare Table 4, p. 10, and Table 9, p. 21).

Fig. 5 illustrates the transplantation experiment. Most specimens were recovered at less depths than at the place of liberation: a natural consequence of the fact that the most intense plaice-fishing is carried on in shallow water. Only a single specimen was recaptured near the Swedish coast.

In autumn, 1904, on September 13th, a single transplantation experiment was undertaken with 40 plaice, which were transplanted from Aalbæk Bay to the deeper part of the northern Kattegat (12 miles E.<sup>3/4</sup>S. of Skagens L. V.).

The plaice were fished at 17 meters depth and liberated at 50 m. As none of the transplanted fish have been recovered later, it may be supposed, that they have all died probably on account of the changed conditions of life. That they should have been weakened during transportation over the relatively short distance from the place of capture to the place of liberation is hardly probable.

The transplanted specimens measured 22—28 cm. The place of capture and the place of liberation did not show any particular difference, neither in the water's temperature nor in the salinity. At the place of capture the temperature was 12·40 C. at the bottom and the salinity was 33·8‰; at the place of liberation the temperature was 12·90 C., the salinity 34·2‰.

**D. The ordinary marking experiments with plaice in the Kattegat  
in the autumn of 1904.**

In the ordinary Danish marking experiments in October, 1904, 360 marked plaice were set free at 9 different places in the Kattegat. The length of the specimens varied between 18—46 cm.; only one specimen was under 20 cm. and only 5 specimens 40 cm. or above.

Particulars regarding the experiments are represented on the Tables 12 and 13. The entries include all recaptures recorded up to the end of September, 1906, and thus comprise a period of ca. 2 years.

In the course of the first year after liberation 184 specimens or 51·1% were recaptured, and until September 30th, 1906, the total recaptures amounted to 201 specimens or 55·8%. Of the specimens between 18—24 cm. the same percentage was recovered as of the specimens between 25—46 cm.

As might be expected the experiments have given the result that the specimens liberated in the northern Kattegat increased considerably more rapidly than those liberated in the southern Kattegat. The former have increased ca. 6 cm. during one year, the latter only ca. 4 cm. (see Chap. III). It should here be remembered that the specimens liberated in the southern Kattegat were for the greater part mature and of a rather considerable size, while the majority of those liberated in the northern Kattegat were immature and of a somewhat smaller size.

Besides the marking experiments mentioned in Table 12, 5 marked plaice were liberated 32 miles SSW.<sup>1/4</sup>W., of Horns Reef light-ship at 45 meters depth on September 28th, 1904. The size of the specimens was as follows: one male: 39 cm., and 4 females: 35, 50, 56 and 57 cm. None of these large specimens are so far known to have been recaptured.

A further account of the results of the marking experiments in the Kattegat in October, 1904, may be looked for in Chap. III of the present paper.

### E. The ordinary marking experiments with plaice in the spring of 1905.

In February and March of 1905, 2000 marked plaice were liberated in the waters surrounding Denmark. In the Horns Reef area 345 were liberated, in the Graadeep inshore waters 40, in the Hanstholm-Søndervig area 40, in the Skagerak 775, and in the Kattegat 800 specimens. Particulars regarding the experiments are represented on the Tables 20 and 21.

The list over the captures of the marked fish is here entered up to the end of September, 1906.

Table 13. Table showing the size of plaice at liberation and the specimens of the various size-groups that have been recovered until Septbr. 30., 1906. The marking experiments in the autumn of 1904.

The specimens liberated in the Horns Reef area were of a length of 21—30 cm. They were caught by the "Thor" and liberated at three different places, either at the very place of capture or in that neighbourhood. 200 specimens were caught and liberated at St. 381, 55°26' N. lat. and 8°02' E. long. at 14 meters depth. 145 specimens were liberated at St. 382 in the North End of Slugen at 55°36' N. lat. and 7°50' E. long. and 15 meters depth. Twenty five of these specimens were caught at the same station where they were liberated, while 120 specimens were transported over a distance of 12 miles from the formerly mentioned St. 381. No difference in the frequency of recaptures was perceived.

Of the 345 plaice 232 or 67.2% were recaptured within one year. 120 specimens were below 25 cm. and gave 59.2% recaptures, and 225 specimens were 25 cm. or above and gave 71.6% recaptures within one year.

In the Graadeep inshore-waters, inside the bar between Fanø and Skallingen, 40 marked plaice

of 23—25 cm. were liberated on April 15., 1905. The recaptures in one year amounted to 28 specimens or 70·0%.

The average increase of the specimens liberated at Horns Reef and Graadeep seems to be ca. 7·5—8 cm. in the course of one year (see Chap. III).

Of the 40 specimens liberated off Torup (near Hanstholm) 35% were recovered within one year. The specimens measured at liberation 23—32 cm. One specimen, recovered 10 months after liberation, had increased 7 cm. (see Chap. III).

In the Skagerak marking of plaice was undertaken at two different localities.

In the area off Bulbjerg-Svinkleven at 10—16 meters depth, 575 plaice of a length of 22—33 cm. were liberated on March 22nd. They were caught by a Danish snurrevaad's cutter and were all liberated near the place of capture. (Experiment No. 4, 1905).

In the course of the first year after liberation 275 marked specimens or 47·8% were recovered. Sixteen of the specimens measured at liberation 22—24 cm. and 559 were 25—33 cm. Of the former, 5 specimens or 31·3%, of the latter, 270 specimens or 48·3% were recovered in the course of one year.

As shown on Table 14 the average yearly increase of the marked specimens has been ca. 7 à 8 cm.; 8 specimens recovered 8—13 months after liberation had on an average increased 7·6 cm. The individual rapidity in growth was here very different; but the monthly averages were rather consistent for the months April—October. The average size of the marked and recaptured fish was at liberation 26—29 cm.

In the Tannis Bay off Spirbakken at 17 meters depth 200 marked plaice measuring from 19—32 cm. were liberated on March 20th, 1905. (Experiment No. 3, 1905). They were all caught by the "Thor" and liberated at the place of capture.

50 specimens were on liberation below 25 cm. and 150 measured 25 cm. or more. Of the former, 7 specimens or 14·0%, of the latter, 49 specimens or 32·7% were recovered within 12 months. Of all the liberated plaice 56 specimens or 28% were recovered in the said time.

As represented on Table 15 the average increase of the specimens during the summer and autumn of 1905 may be estimated at ca. 6 à 7 cm. Two specimens recovered in January, 1906, only showed an increase of 3 and 3·5 cm. in length. The recovered specimens measured on liberation 23—31 cm. and belonged evidently essentially to the III-Group.

Table 15. Rate of Growth of plaice liberated in Tannis Bay (Skagerak). March, 1905. Marking Exper. No. 3, 1905.

On March 29<sup>th</sup> 300 marked plaice of a length of 22—33 cm. were liberated in Aalbæk Bay NW. of Hirsholmene at 16 meters depth. All the specimens were caught by the "Thor" and liberated at the place of capture. They were all, or almost all, immature fish (Exper. No. 6, 1905).

121 of the specimens measured on liberation less than 25 cm. and 179 more than 25 cm. Of the former were recaptured in the course of one year 61 specimens or 50·4%; of the latter 109 specimens or 60·9%. Of all the liberated plaice 170 specimens or 56·7% were recovered in one year.

This percentage is much less than in the marking experiments in 1904 in Aalbæk Bay, where 2 experiments with 40 and 26 specimens gave respectively 92·5% and 92·3% of recaptures within one year.

To form a judgment about the normal percentage of recaptures in Aalbæk Bay it is of importance to notice that the experiment of March 29., 1905, was apparently not quite successful. Seven days after liberation 2 marked plaice were hauled up from the sea-bottom by a fisherman, who found them to be "dead and rotten" (see p. 18). Thus it is evident that some of the specimens had sustained injuries either during the process of marking or during the process of capture (by pricks of sea-urchins? A considerable number of *Strongylocentrotus droebachiensis* were taken together with the plaice).

The growth of the liberated specimens appears here to have been rather inconsiderable during the summer. 4 specimens recaptured 7—14 months after liberation had on an average only increased 4·4 cm. On the basis of these few specimens however, we dare not draw the conclusion that the plaice in Aalbæk Bay on the whole increased so slowly in 1905. The investigation of the otoliths does not point in that direction<sup>1</sup>.

<sup>1</sup> A. C. JOHANSEN: Ueber die Schollenfischerei im Kattegat und die Mittel, sie zu heben. Rapports et Procès-Verbaux Vol. V. 1906. Conseil perm. internat. pour l'exploration de la Mer. p. 92.

On March 15., 1905, 95 plaice were liberated 5 miles N. of Anholt light at 19 meters depth. One specimen measured 48 cm. and the remaining 26—38 cm. The majority of the specimens were immature fish of the "northern form" (Exper. No. 1, 1905).

Within the first year after liberation 70 specimens or 73·7% were recaptured.

The growth of the recovered marked fish is represented in Table 17. The monthly averages show a rather regular increase from March, 1905 to January, 1906. The increase amounts in the course of the summer to ca. 5 cm.

Table 17. Rate of Growth of plaice liberated N. of Anholt. March, 1905. Marking experiment No. 1, 1905.

In Aalborg Bay at 56°48' N. lat. 10°35' E. long. and 9 meters depth, 100 plaice measuring 21—33 cm. were liberated on April 1<sup>st</sup>, 1905. Most of the specimens were on liberation immature fish of the "northern form" (Exper. No. 7, 1905).

47 of the specimens were below 25 cm., while 53 specimens measured 25 cm. or above. Within one year 19 specimens or 40·4% were recovered of the former and 28 specimens or 52·8% of the latter. Of all the 100 specimens 47% were recovered in the course of one year.

The growth of the recovered specimens is represented in Table 18. It appears from the Table that 10 specimens, which were recovered within 9—14 months after liberation, had on an average increased 6·6 cm.

Table 18. Rate of Growth of plaice liberated in Aalborg Bay. April, 1905. Marking experiment No. 7, 1905.

Near Anholt, SW. of the isle at 15 meters depth, 305 marked plaice were liberated on March 16<sup>th</sup> and 17<sup>th</sup> of 1905. Five specimens were between 21—24 cm., 293 between 25—34 cm. and 7 between 35—43 cm. Most of the specimens were caught by some Danish snurrevaad cutters and liberated near the place of capture. The majority were immature fish of the "northern form" (Exper. No. 2, 1905).

During the first year after liberation 210 specimens or 68·9% were recovered. The growth of the specimens is represented in Table 19. It will be noticed that 14 specimens of a length of 26—35 cm., recovered 9—15 months after liberation, showed an average increase of 5·5 cm., which must be regarded as a considerable growth for plaice of that size.

### F. The ordinary marking experiments with plaice in the Graadeep inshore-waters in the autumn of 1905.

In the Graadeep inshore-waters between Esbjerg and Skallingen 21 marked plaice of 20—26 cm. length were liberated on September 29th and 30th of 1905. Within one year 7 specimens or 33·3% were recaptured.

A detailed record over particulars of liberation and recaptures is represented on Table 22. It will be seen that only three of the liberated specimens were recaptured during the inshore fishing in the autumn. Next spring and summer 4 specimens were recaptured in the North Sea and one of those by a foreign trawler.

The length of the liberated specimens was as follows:

	males	females		males	females
20 cm. ....	5	2		24 cm. ....	3
21 " ....	..	3		25 " ....	..
22 " ....	1	2		26 " ....	1

### G. The ordinary marking experiments in the Horns Reef area in April of 1906. Preliminary record.

On April 7th and 10th of 1906, 200 marked plaice of a length of 24—31 cm. were liberated in the Horns Reef area near Slugen. Until the end of September, 1906, 126 specimens or 63% were recovered.

As is usually the case in the Horns Reef area a far greater percentage was recaptured of the larger than of the smaller specimens. At liberation 180 specimens measured 25 cm. or above, while the length of 20 specimens only was 24 cm. Until September 30th, 1906, 121 specimens or 67.2% were recovered of the former, and 5 specimens or 25% of the latter.

## III. Discussion of the Results of the Danish marking experiments with plaice in the years 1903—1906.

### A. Rate of growth of plaice.

The growth of plaice varies according to the stage of development as well as to the density of "population" and to the locality where they live. In the larger specimens a considerable difference in the rate of growth may be noticed in the two sexes, the females increasing with far greater rapidity than the males. It is hardly the most common case that the plaice increase in growth with the greatest rapidity during their first year. Very frequently a more rapid growth may be traced in the second or third year of their life. On approaching maturity there is a considerable decrease in growth, and the mature specimens grow on the whole with far less rapidity than the immature ones.

### 1. Rate of growth of plaice of different sex.

As will be seen in the Tables 23 and 24 the specimens of the two sexes of the plaice of the "northern form"<sup>1</sup> increase in growth with about equal rapidity as long as they are below 30 cm. At a size of 30—34 cm. the growth is already considerably quicker in the females than in the males. Through investigations of the otoliths it may be proved that the growth in smaller specimens also is a little more rapid in the females than in the males.

Table 23. Rate of Growth of plaice of different sex. Marking and Transplantation experiments in the Horns Reef area. February, 1904. (Mark. exper. No. 1, 2 and Trpl. exper. No. 1—9).

<sup>1</sup> I use the term "northern form" for the plaice which have their home in the northern part of the North Sea, the Skagerak, and a part of the northern Kattegat, in opposition to the "southern form" or the "dwarf-form" whose home is the southern Kattegat, the Belt Sea and the Baltic. This dwarf-form has been mentioned in various papers by HOLT, DUNCKER, MORTENSEN, PETERSEN, KYLE a.o.

## 2. Rate of growth of plaice in the Horns Reef area.

The Danish marking experiments have revealed a fact of great importance, namely that plaice of the same size may in different years grow with very unequal rapidity on the same fishing grounds.

As will be seen in the Tables 26, 27, 28 the marking experiments show that the rate of growth of plaice in the Horns Reef area has been greater in 1904 than in 1903, and still greater in 1905 than in 1904. The difference is so conspicuous that it may not be mistaken. The monthly averages are sufficiently consistent with one another to make us believe that we have for all the three years determined the rate of growth on a fairly solid basis.

The experiments in spring of 1903 showed a rate of growth of 4–4·5 cm. in one year. In the experiments in spring of 1904 the increase in growth was in one year ca. 6 cm., and finally in the experiments in 1905 the growth was in one year 7·5–8 cm.

As it has become evident that the young plaice grow relatively slowly in places where they are exceedingly numerous, and relatively quickly where they are more scarce, it might seem an obvious conclusion that the unequal rate of growth might be due to an unequal density of population, the density decreasing in the years from 1903 to 1905. If this be the reason of the unequal rapidity in growth, it must be supposed that the diminishing density is a phenomenon which has only been of consequence for the young, not yet marketable, plaice. It appears namely that in 1903, when the plaice in the Horns Reef area increased slowly, the Esbjerg cutters' yield of the plaice-fishery — which essentially is carried on in this area — was comparatively slight, while the yield was considerably greater in 1904 and 1905 when the rapid growth took place (see Table 25).

At the same time as we trace a relatively rapid growth of plaice, namely in the month of July, 1904, the Esbjerg cutters begin to get a relatively rich yield.

Thus we must suppose that a proportionately larger number of marketable plaice (above 25 cm.) has been present in the Horns Reef area in 1904 and 1905 than in 1903. That the yield of the fishery becomes considerable in the years where a rapid growth takes place may naturally be understood from the consideration that proportionately many undersized fish grow up to a marketable size.

It is also worthy of note that in 1902, when the yield of the plaice-fishery at Horns Reef was uncommonly rich (see Table 25), the rapidity of growth for the plaice has probably also been very considerable. We have, namely, ascertained by investigating otoliths of plaice recovered in the Horns Reef area in April, 1903, that a great part of the specimens at a size of 25–28 cm. (see Contributions I p. 8, Stat. 38–39–41) were only 3 years old. It is probable that such specimens in the course of their third year, i. e. in 1902, have increased about 10 cm. in growth. It may however be admitted that we do not know if these specimens have lived in 1902 on the Horns Reef grounds or if they have come from other areas.

These investigations have thus afforded some reason to suppose that there is a connection between the rapidity of growth of the plaice in the Horns Reef area and the yield of the plaice-fishery in this area. Future investigations may elucidate this matter further. The possibility is not yet excluded that the small yield of the plaice-fishery in the Horns Reef area in 1903 and the proportionately great yield in 1902, 1904 and 1905 may be due to other causes than those here mentioned (see the section B).

In the Table below, which has been compiled from the Danish "Fiskeri-Beretning", a summary is given over the monthly yield of the Esbjerg cutters plaice-fishery in the years 1897–1905<sup>1</sup>. As fishing unit we have chosen a "cutter day", a term which should be understood in the following way. The number of cutters fishing in a month has been multiplied by the number of "fishing days", which

<sup>1</sup> The statistics for the Esbjerg fishery are very important as the original data have been collected with great care (by Mr. LORCK MADSEN).

means the days when the weather has allowed fishing by snurrevaad. The product is the number of cutter days. If for instance it is stated, that 75 cutters have been fishing in a month and that there have been 10 "fishing days" the number of "cutter-days" will for that month amount to 750: a somewhat higher figure than we would get if we knew the exact number of fishing days for each cutter separately.

It may be seen in Table 25 that the yield has been far less in 1903 than in 1902, 1904 and 1905, both when we regard the total yield and when we consider the yield per cutter-day. It is moreover interesting to notice, that while the total yield has on the whole increased in the course of the years 1897—1905, the yield per "cutter-day" has on the whole decreased, and this in spite of the fact that the cutters' fishing power has been greatly improved.

Table 25. The catch of plaice by the Esbjerg cutters in the years 1897—1905.

The fact that the plaice on the same fishing grounds may increase in length with very unequal rapidity in different years makes the question about profitable transplantation of plaice in the sea rather complicated.

As will be seen in the Table 29, the plaice of 25—29 cm. seem to increase in size with a similar rapidity to those of 20—24 cm. in the Horns Reef area.

### 3. The Rate of Growth of plaice in the Hanstholm—Søndervig area.

To judge from the relatively few specimens which are represented in Table 30 the increase in growth of the plaice of 22–35 cm. liberated in the Hanstholm—Søndervig area may be put down to ca. 8 cm. for the year 1903, or about twice as much as the increase of plaice in the Horns Reef area in that year.

From the marking experiments in 1905 there are so few recaptures that we cannot settle with any certainty how great the normal increase has been in the course of one year, but it is reasonable to suppose a somewhat similar increase to that in 1903 (see Table 31).

### 4. Rate of growth of plaice in the Skagerak.

The rate of growth of the plaice which were marked in the Skagerak in April, 1903, March, 1904, and March, 1905, is represented in the Tables 32, 33, 34.

From the experiments in 1903 we know only the yearly increase in growth of the small specimens of 16–24 cm. The growth appears in the course of one year to have been at least 10 cm. for these. A considerably less rapidity of growth may be noticed in the transplantation experiments in 1904 for specimens of 22–27 cm., and in the ordinary marking experiments in 1905 for specimens of 23–30 cm., namely ca. 7–8 cm. The difference in the initial size in the specimens from the experiments in 1903 and the two series of experiments in 1904 and 1905 is, however, so considerable that it may play an essential rôle in comparing the rate of growth.

It will be seen in the Tables 35 and 36 that though the specimens exceeding 30 cm. have had a less rapidity of growth than the smaller specimens their increase in length is still quite considerable.

In the experiments of 1903 the growth of specimens of 30—36 cm. appears to be at least 4 cm. for the period from April to September. In the experiments of 1905 four specimens of a length of 30—33 cm. increased during 7—11 months on an average 5·5 cm.

##### 5. Rate of growth of plaice liberated in the Kattegat.

A view is given over the rate of growth of the marked plaice in the Tables 37—43. The yearly increase in growth has been as follows for plaice from the northern and middle Kattegat:

for specimens of length from 21—31 cm. liberated in March, 1904, ca. 7 cm. (Table 37).

for specimens of length from 20—39 cm. liberated in October, 1904, ca. 5 cm. (Table 38 A & B).

for specimens of length from 22—37 cm. liberated in March, 1905, ca. 6 cm. (Table 39).

As the specimens have been of very unequal size and as they were liberated in rather different localities, the Tables 37—39 do not show how far the growth of the plaice in the northern and middle Kattegat has been different in the two years 1904 and 1905.

If we regard Table 40, which comprises solely specimens of 22—29 cm., liberated in the Aalbæk Bay or in the vicinity in March, 1904 and March, 1905 we get the impression that the plaice have here grown with a somewhat greater rapidity in 1904 than in 1905.

Table 40. Rate of Growth of plaice of initial length 22—29 cm., liberated in Aalbæk Bay or Hertha's Flak in March, 1904, and March, 1905.

Month recovered	Period between Liberation and Recovery	Experiment March 1904		Experiment March 1905	
		Average increase	No. of specimens	Average increase	No. of specimens
June .....	3 months	1·8	5	1·0	18
July .....	4 »	4·0	3	2·0	9
August .....	5 »	3·5	1	0·7	3
October .....	7 »	6·5	1	6·0	1
January .....	10 »	...	..	3·5	1
May .....	14 »	...	..	3·5	1

In the experiments in the northern and middle Kattegat it has become evident that the specimens increase in growth with rather considerable rapidity till they reach a size of ca. 35 cm. The specimens which surpass this size are either mature or approach maturity for the first time, and the growth becomes now considerably slower than in the younger and smaller specimens. In the experiments in the middle Kattegat in March, 1905, the following growth might be noticed in the specimens which were recovered 9—14 months after liberation (see Table 41).

7 specimens of 22—25 cm. increased on an average 5·9 cm.							
5	»	»	26—29	»	»	»	8·9
11	»	»	30—34	»	»	»	4·9
3	»	»	35—37	»	»	»	1·5

The figures stated here might seem to show that the yearly increase is greater for the specimens between 26 and 29 cm. than for the specimens between 22 and 25 cm. We are, however, not entitled to fix the yearly increase solely according to the few specimens that are recovered about a year after liberation. If we regard the total monthly averages the impression is conveyed that the specimens of the latter group have increased as quickly as the specimens of the former group. (Table 41.)

The experiments in 1904 and 1905 suggest in reality that the yearly average increase for plaice of 20—29 cm. amounts to at least 7 cm. in the northern and middle Kattegat.

For plaice of a length from 26—39 cm. from the southern Kattegat liberated in October, 1904, the increase in growth has in the course of one year only been ca. 4 cm. (Table 42) but it should be remembered here that the majority of these specimens were already mature at liberation, while the great majority of the specimens from the northern and middle Kattegat had not reached maturity at liberation.

In one of the experiments in the southern Kattegat (No. 14 A) only mature females were liberated of a length from 26—36 cm. It appears from Table 43 that the yearly increase for such specimens has not been more than ca. 2 cm.

As the female plaice in the southern Kattegat reach maturity for the first time generally at a size of ca. 20—30 cm. and at an age of 3—5 years, we must suppose that mature specimens of a length of 40 cm. or above are of a very considerable age as far as they have grown up in this water.

Table 43. Rate of Growth of mature female plaice in the southern Kattegat.

## B. Migrations of Plaice.

Long ago the fishermen have experienced that the plaice undertake migrations, and they have formed different hypotheses about the characters, extent and causes of these migrations. Some of these hypotheses are mentioned by the older authors who treated the question about the migration of the plaice. KRØYER<sup>1</sup> writes for instance on the basis of the fishermen's experiences that the plaice twice a year migrate out into deeper water, namely in warmest summer and coldest winter, and that they likewise twice a year approach the coasts, namely in spring and autumn. As will be mentioned later on, the Danish marking experiments in 1903—1905 have essentially confirmed this view and have in no way been at variance with it.

By the systematical investigation of the frequency and distribution of the various age-groups of plaice, which have been carried on in the North-European waters in the last decennaries some light has been thrown over the migration of the plaice. One of the most principal facts which has been revealed is that the youngest bottom-stages of the plaice are only met with on quite shallow water close to the shore. While the grown up plaice occur almost everywhere in our waters from the coasts to 50 fms. or exceptionally to 100 fms. depth, the youngest bottom stages are in the main restricted to depths below one fathom and are rarely met with in a few fathoms depth<sup>2</sup>. When

<sup>1</sup> HENRIK KRØYER: "Danmarks Fiske" Bd. II. Kjøbenhavn 1843—45, p. 272.

<sup>2</sup> Particular conditions exist in the true Baltic Sea where specimens of the 0-Group are very rare in shallow water, below 4 meters, but fairly numerous at depths from ca. 10—40 meters (according to the recent investigations of the "Thor").

this has been ascertained, we must conclude that the plaice which occur far from the coast must have undertaken long migrations previously. By investigating the distribution of the 0-Group, the I-Group, the II-Group, etc., it has also been found that gradually as the plaice increase in size they move out into greater depths and thereby enlarge their area of distribution.

Among other information concerning the migration of the plaice, which has been obtained by the systematical investigation of the distribution of the different age-groups, it should be mentioned that the plaice in the Lim Fjord come from the North Sea. Dr. PETERSEN has namely found that the youngest bottom-stages immigrate through the Tyborøn Canal, and gradually as the plaice increase in size they migrate further eastward. The youngest bottom stages are wanting, or at any rate very rare, in those parts of the Lim Fjord where the great plaice-fisheries are carried on: Kaas Bredning, Livø Bredning etc.

In the marking experiments, which were commenced in the North-European waters in 1887 by Dr. PETERSEN<sup>1</sup>, as a link in the rational investigations of the stock of food-fishes in the sea, and which in later years, after the beginning of the international cooperation for the study of the sea, have been carried on to a great extent, much light has been thrown upon the migratory tendency of the plaice, and as a general result of these investigations it may be said, I think, that the plaice is much more a fish of migratory habits than was believed formerly by most of the older naturalists.

With respect to the special information about the migrations, which the Danish experiments in 1903—1905 have afforded, the summary below must be referred to.

While it on one hand should be remembered that the number of plaice captured in a certain area depend highly on the intensity with which the fishing is carried on, it must on the other hand not be forgotten that the intensity with which the fishery is carried on in the different areas depend essentially upon the migration of the plaice.

### 1. Migration of Plaice liberated in the Horns Reef Area.

In order to obtain a view over the migrations of the plaice through the marking experiments it is not sufficient to know at which places and at what time the marked plaice are recovered. It is also necessary to know at which places and with what intensity the fishery is carried on in the different seasons. Information in the latter direction is not difficult to obtain as far as the Danish plaice fishing in the Horns Reef area is concerned, owing to the fact that the "Dansk Fiskeritidende" states in weekly accounts where the cutters are fishing.

A view over the places where the cutters, which take their catch to Esbjerg, have been fishing during the years 1903—1905 is represented in Table 44. As the great majority of the recovered marked specimens in the Danish experiments have been captured by the Danish cutters, it is of less importance to us that it has not been investigated on which grounds the English and German trawlers have been fishing during the different seasons.

Table 44. Table showing the Localities, where the Esbjerg Cutters have been fishing in 1903—1905.

It may be seen from Table 44, that the cutters keep about the same grounds during the same season in the different years.

The fishery around or SW of Vyl light-ship commences at the end of February or at the beginning of March. Later on, in March or April, a great many of the cutters move into more shallow water and approach the Graadeep and Cancer. Yet in April only a few cutters sail north of Horns Reef. In May and June many cutters go north of the Reef, where they remain in the beginning on rather shallow water below 25 meters, while they later on generally fish at depths from 25—40 meters. The cutters

remaining south of the Reef now fish the grounds further south off Amrum and Sylt, or stand further to sea.

During the summer months July, August and partly in September, when the water is warmest, very little fishing takes place on the grounds near the Horns Reef below 20 meters depth. The majority of the cutters are fishing somewhat further out partly off the stretch Haurvig—Aargab—Sønder Lyngvig—Søndervig—Husby—Bovbjerg, partly at Horns Reef light-ship or NW. of that, and partly in a south-western direction from Graadeep, ca. 30—80 miles at sea. At the end of September or in the beginning of October the cutters recommence to gather at the Horns Reef grounds, where they are now fishing, partly north of, partly south of the Reef, until the cutter fishery ends in the month of November.

In November and December a rather considerable plaice fishery takes place in the inshore waters at Esbjerg from small boats. This fishery ceases when the winter cold sets in.

The question is now: what conditions cause the rather uniform movements of the fleet of fishing vessels in the different years. It should be noticed that when the cutters in spring, in February or in the beginning of March, start the fishery, they do not begin on the quite shallow water at Graadeep and Cancer, but they sail further out and begin S. or SW. of Vyl light-ship. Though the unsettled weather of this season might tempt the cutters to look for the fish as near the harbour as possible, they go several miles out. Thus the fishermen must evidently have experienced, that they may reckon with a richer catch here than on the shallow grounds at Cancer and Graadeep. Not until they have been fishing around Vyl for a time do they sail into the more shallow water at Graadeep, Cancer and Slugen. That the cutter's movement towards the more shallow grounds is owing to a corresponding movement of the plaice, we have every reason to believe, as it has been ascertained, that a very great portion of the plaice which in spring were marked at Vyl or somewhat further at sea have later on been recovered in the shallow water at Cancer, Graadeep and Slugen (see Contributions I, Pl. XI and XII and this paper Fig. 3 p. 16 and Pl. V and VI).

When the fishermen in the beginning of the summer generally leave the grounds at Horns Reef to stand further at sea we might imagine the following reasons to account for this:

- 1) That the stock of marketable fish at the Horns Reef had been fished up.
- 2) That the stock of marketable fish was migrating outward into deeper water.

That the stock of marketable plaice at Horns Reef is not quite destroyed by the spring fishery is proved by the Danish marking experiments. A not inconsiderable number of the specimens marked at the Horns Reef grounds escape recapture at these grounds in the spring, while they are partly recovered in deeper water in summer. Thus the cutter fishery in summer is at least partly based on a stock coming from the Horns Reef. In this way we must suppose the migrations of this stock to influence the cutter's movements.

It would also appear from the trawling experiments carried on by the Danish, English and German research steamers, as if the quantity of plaice on the off-shore grounds in the Horns Reef area at depths above 30 meters mainly depend on the stock of young plaice that in the summer months comes from the shallow water. In March, April and May there are very few plaice on the off-shore grounds, and the Danish cutters do not fish there. In July, August and September there are relatively many plaice on the off-shore grounds, which are now visited by the Danish cutters (conf. GARSTANG: Provisional Report on the Natural History of the Plaice etc. Rapports et Procès-Verbaux, vol. III, 1905).

In July of 1903 the majority of the Esbjerg cutters fished 30—80 miles WSW. of Graadeep, but they did not catch more than one of the Danish marked fish here (see Contributions I, Pl. XI and XII). A few cutters fished on the other hand N. or NNE. of Horns Reef light-ship, and caught two marked fish. The trawlers captured 7 of the marked fish in the same month, and most of these were recovered

NW. of Horns Reef light-ship. Thus it appears as if the plaice have moved mainly in a north-western direction when they have migrated out towards greater depths.

The Figures 2 (p. 14), 3 (p. 16), 6 (p. 78) and 7 (p. 79) offer a view over the migrations of plaice which were liberated in the Horns Reef area in February, 1904. It is of great interest to notice where the marked fish were caught during the month of July (see the arrow heads marked 5 on Fig. 2, 3, 6 and 7). The cutters fished partly SW. of Horns Reef, 30—40 miles or more from shore, partly northward, off the area Nyminddegab—Bovbjerg. In the former places no marked plaice were recovered, in the latter 8 specimens. Thus it is quite evident that the plaice migrating away from the Horns Reef grounds have moved in the main in north-western and northern direction as in the summer of 1903.

Turning to the marking experiments No. 8, 9 and 10 in April, 1905 (Pl. III, V and VI) it will be seen also that far more marked fish were recovered during the summer period, July, August, September, north-west than south-west of Horns Reef (arrow heads marked 3, 4 and 5), and yet the cutters seem to have been fishing as much south-west as north-west of Horns Reef. It is also here plain that the fish from Horns Reef have moved in north-western direction in summer. The cutters, which in summer have fished south or south-west of the Reef, have probably not caught plaice coming from the Horns Reef, but more likely fish migrating from south.

In the beginning of autumn the cutters leave the deeper water and start again for the Horns Reef grounds. This movement is probably due to the following three causes.

1) That some of the plaice have returned from the off-shore grounds.

This hypothesis is in accordance with the fact that the marked fish may sometimes in autumn be recovered near the coast in

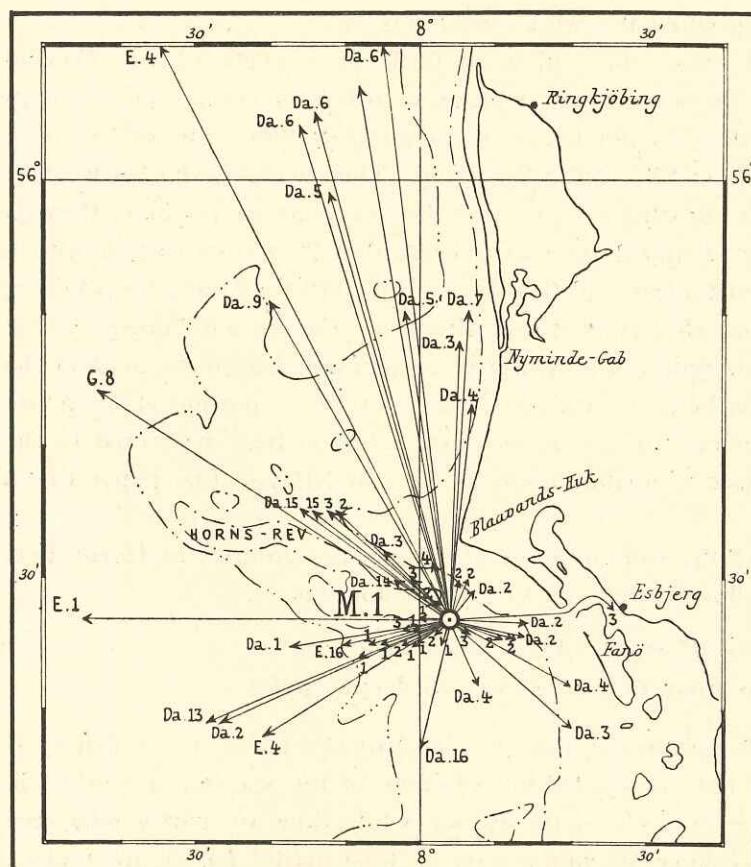

Fig. 6. Marking experiment with plaice. No. 1. 1904. February.

more shallow water than that in which they were liberated, while they are in summer constantly caught further in the offing. During the inshore fishing in Graadeep in the month of November, 1903, 3 specimens were thus recovered of those liberated in spring at Vyl or at Horns Reef. This points undoubtedly in the direction that at any rate some of the plaice gathering in the Graadeep inshore waters in autumn come from deeper water in the very North Sea.

It is worthy of note that three specimens recovered close to the shore in October—November had only an average length of 24 cm., while 6 specimens caught on the off-shore grounds in September—December had an average length of 29 cm. We see here an illustration of the fact that it is especially the larger specimens which remain on the off-shore grounds in autumn and winter.

2) That some of the plaice which in the course of the summer have reached a marketable size at the Horns Reef grounds have remained there.
