## I. Introduction.

### Material of observations.

FOR some years the lack of a research steamer made it impossible from Danish side to undertake fishing experiments in the open North Sea and it was only possible to investigate the varying density and growth of the plaice population by means of information afforded by the fishery statistics and by the examination of marketable plaice. Although these means enabled one to follow in broad outlines the changes produced by the war conditions, yet one felt very keenly the need for more direct information in order to give a detailed picture of the present composition of the plaice population in the Horns Reef area, where the Danish plaice fishery in the North Sea mainly takes place. Therefore on the first cruise in the Danish waters with the new research steamer "Dana", one of the chief tasks was to carry out fishing experiments with special regard to plaice.

During the cruise in September 1922 Dr. A. C. JOHANSEN worked 33 Stations in the Horns Reef area from the coast to 5°39' E. L. and between 55°00' and 56°08' N. Lat. (laid down in Fig. 2). The apparatus used was a 50 feet otter-trawl with extra cod-end and the experiments lasted from  $\frac{1}{2}$  hour to 2 hours at each station, all the plaice caught being counted and as a rule measured. At most of the stations the age was determined from the otoliths and the sex noted for all individuals, excepts those of the 0-group. But at 12 stations, where the catches were very large, the age and sex were determined for a portion only of the specimens occurring in the length groups most frequently represented, and the remainder of the specimens were distributed in proportion to those examined. The observations are fully recorded in the Tables of Measurements A.

As a supplement to the fishing experiments, a series of measurements of marketable plaice from the Horns Reef area, landed in Esbjerg, was carried out during September to November 1922, chiefly in October. A total of 23,299 plaice were measured, distributed among 247 samples, of which 145 belonged to catches taken in the part of the international area B<sub>4</sub> situated north of Horns Reef, this part of B<sub>4</sub> being, at the time, much richer of marketable plaice than the still more densely populated area west of Graa Deep. The measurements are recorded in Table of Measurements B.

Finally Dr. A. C. JOHANSEN has placed at my disposal the records of the marking and transplantation experiments carried out in the Horns Reef area during 1920 and 1921, of which a full record will not be given, but only the abstract contained in the figures and tables of section VI.

## II. Density of plaice.

From the Tables of Measurements A the number of plaice of each age-group caught per hour by a 50 feet otter-trawl has been calculated and the results are represented in Fig. 1. Fig. 2 gives the total number of individuals caught per hour. The figures vary considerably even amongst neighbouring stations, and a clearer view is obtained by considering average values for groups of stations. We therefore grouped the stations according to six areas, bounded in the following way:

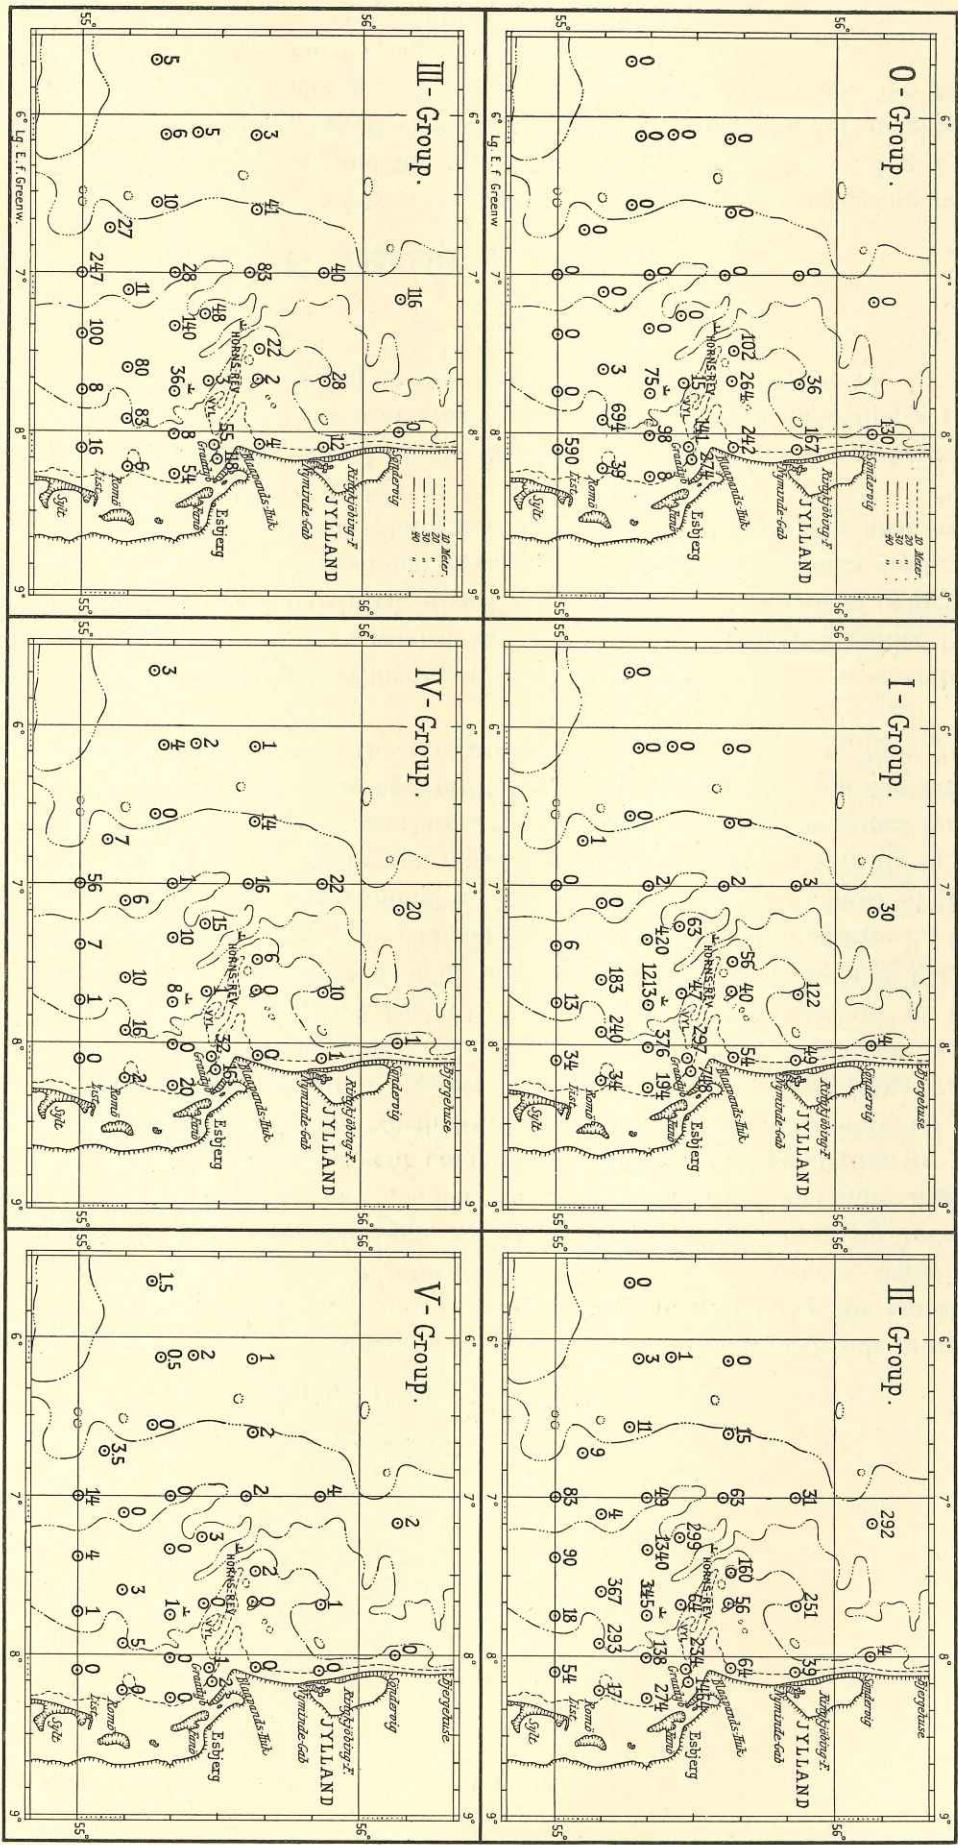

Fig. 1. Showing number of plaice of each age-group caught per hour by a 50 feet otter-trawl with extra cod-end. — September 1922.

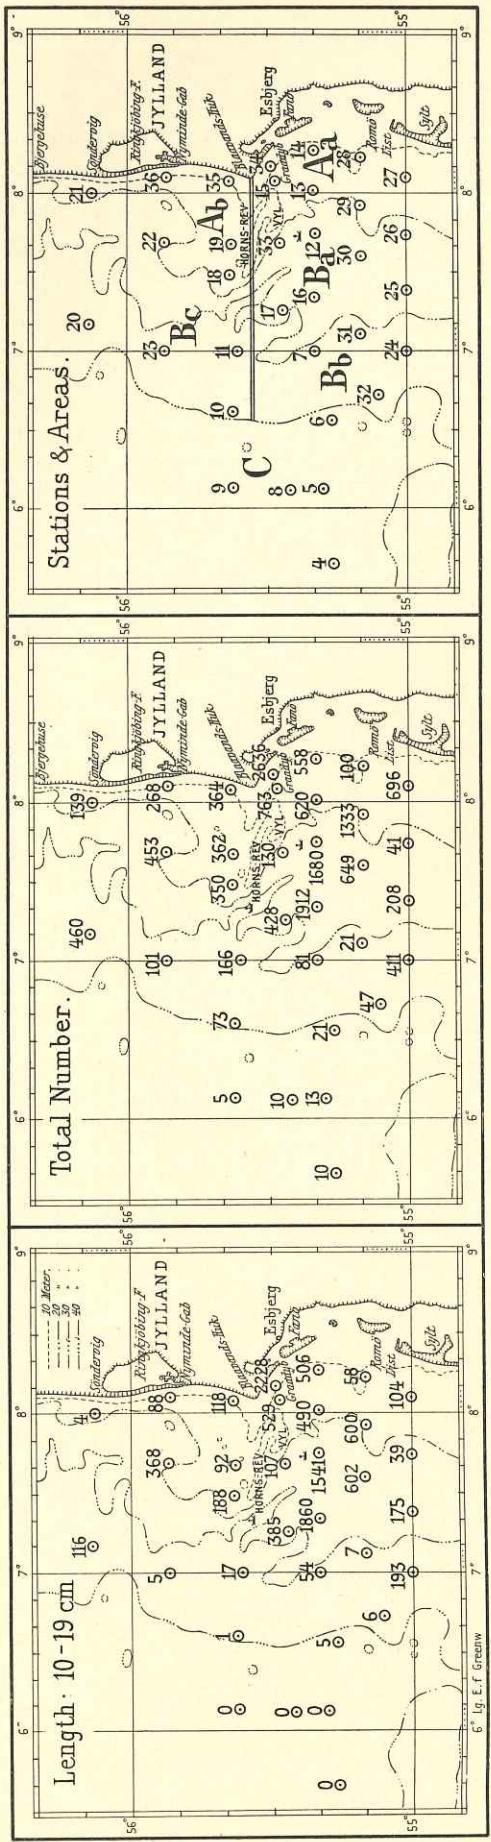

Fig. 2. Showing: (1) Number of plaice of the length 10–19 cm, (2) total number of plaice caught per hour by a 50 feet otter-trawl (with extra cod-end), and (3) stations (designated by their numero minus 2800) and areas used in the present paper.—September 1922.

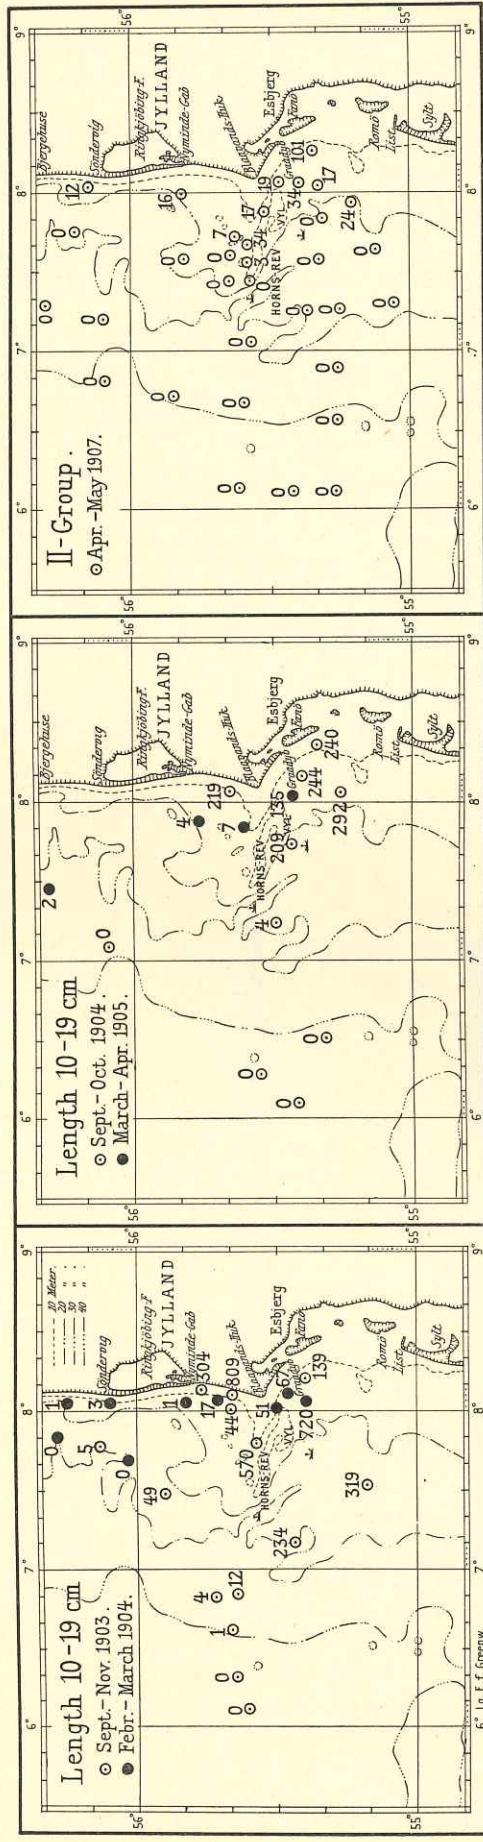

Fig. 3. Showing number of plaice within given size limits or of given age caught per hour by a 50 feet otter-trawl with extra cod-end.

a. Variation of density in September 1922 according to locality.

The charts of Fig. 1 illustrate clearly the well-known fact that the young plaice live near to the coast and gradually, as they grow older, move to the greater depths and spread over greater areas, some of the older specimens still remaining in the coastal area.

The 0-group is, in September, found largely in the areas  $A_a$  and  $A_b$ , and it is not caught at greater depths than 23 metres. On the whole, it is not much more frequent in  $A_a$  than in  $A_b$ . Each of the other age-groups is on an average, of equal density in  $B_a$  and  $A_a$  and in these areas, it is several times as numerously represented as in  $A_b$ . Therefore within the 20 metres depth-curve the total density of the plaice population, as measured by these catches, is three times as large south of Horns Reef as north of Horns Reef. The I- and II-groups are most frequent in  $A_a$  and  $B_a$ , and they have both of them, in a northerly to southerly direction, a maximum density about west of Graa Deep. The I-group does not occur in depths of more than 36 metres. The II-group is met with at all the stations except two of the most westerly. The III-, IV- and V-groups are especially frequent in the areas  $A_a$ ,  $B_a$ ,  $B_b$ , and  $B_c$ . Outside the 20 metres curve they are not essentially more numerous in the southern ( $B_a$  and  $B_b$ ) than in the northern part ( $B_c$ ) of the waters investigated, and in the northerly to southerly direction, no maximum of density is observed for these age-groups.

We have compared here the density of the same age-group in various areas, but if instead, we group the plaice according to size and for instance ask for the density of marketable plaice, we arrive at quite another result because of the different growth rate north and south of Horns Reef. The density of marketable plaice will be dealt with in section V.

b. Comparison of density in 1922 with density during the period 1903—1907.

From Danish side no experiments of fishing with otter-trawl have taken place since 1907, and the examination of otoliths was not generally carried out before the summer of 1905. Therefore from the fishing experiments undertaken in 1903 and 1904 and in the spring of 1905, we have no measure of the density of separate age-groups, but we may, for plaice of a given size-group, compare the density found in 1922 with that found at the earlier period.

In Fig. 2 and Fig. 3 the frequencies of plaice of lengths 10—19 cm are represented. It will be seen from these charts, that, in September 1922, the density of such plaice was in the areas  $A_a$  and  $B_a$ , three times as great as it was in the autumn of 1903 and of 1904 and in the spring of 1904 and of 1905. In  $A_b$ , however, the density of these plaice appears smaller in September 1922 than in the autumn of 1903 and of 1904, but, on the other hand, the experiments during the spring of 1904 and 1905 show a still smaller density than the experiments in 1922. In C and the outer parts of B plaice of these sizes are scarce, and there is no evidence that they were more numerous in 1922 than in the earlier period.

As will be seen from the next section, the growth of plaice in the Horns Reef area has, in 1922, been extraordinarily small, from which it follows, that the size-group 10—19 cm was not of the same composition as regards age in 1922 as in the autumns of 1903—1905. It is therefore essential to elucidate as far as possible, whether, or to what extent, this fact might account for the great difference of density observed for the areas  $A_a$  and  $B_a$ .

We shall first consider the age of plaice of the lengths 10—19 cm in September 1922. If we add together the plaice caught per hour at all the stations, we find that in this sum the specimens of 10—19 cm cover (1) the I-group except a few (6 %) of the smallest, (2) the II-group except a few (7 %) of the largest, and (3) about half (51 %) of the III-group. The lengths of plaice of the same age, however, differ in the various areas. In  $A_b$  and the most northerly part of  $A_a$  the number of plaice of 10—19 cm equals the number of individuals belonging to the I- and the II-groups, but in the southern part of  $A_a$  and  $B_a$  this

particular size-group is more numerous than the two age-groups, because it contains also an essential part of the III-group, on the other hand in C and the outer regions of B<sub>a</sub>, plaice of the lengths 10—19 cm do not comprise all plaice of the II-group, which here contains individuals longer than 19 cm. In the northern parts of A<sub>a</sub> and B<sub>a</sub>, where the fishing experiments in 1903—1905 took place, the number of plaice of the lengths 10—19 cm in 1922 only exceeds the total of the I- and II-groups by 3 per cent.

According to the results from two stations from A<sub>a</sub> and B<sub>a</sub> investigated in September 1905<sup>1</sup> the plaice of 10—19 cm at that time comprised only the I-group and about two thirds of the II-group. From the experiments<sup>2</sup> of marking it is known that the growth rate was exceptionally quick in 1905, viz. 8 cm, and in the foregoing years slower, viz. 5.5 and 4.0 cm. It may therefore be assumed that plaice of the lengths 10—19 cm in the autums of 1903 and 1904 comprised at least as great a part of the II-group as in 1905. The growth rate appears to be less variable from year to year for the I-group than for the older fish, so that we may reckon that it contains in the autums of 1903 and 1904 practically no specimens smaller than 10 cm. Assuming the I-group and the II-group to be of equal frequency in the catches, and assuming the density of each year-group to be equal in the two periods compared, we should, according to the altered rate of growth, expect the density of plaice from 10—19 cm to have increased by the ratio

$$\frac{1+1}{1+\frac{2}{3}} = \frac{6}{5}.$$

Instead of this we have found that the density of this size-group in the northern parts of A<sub>a</sub> and B<sub>a</sub> has been trebled, and there is, therefore, no doubt that both the age-groups I and II in these waters have been represented by much greater numbers in 1922 than in 1903 and 1904.

Table 2. Number of Plaice Caught per hour by a 50 feet otter-trawl with extra cod-end. Sept. 25.—30. 1905.

<sup>4</sup> „ „ 244 „ „ „ „

<sup>5</sup> „ „ 219 „ „ „ „

From September 1905 samples whose age has been determined from the otoliths are available from a few stations in the Horns Reef area. The catches per hour are given in Table 2. It will be seen that at Station 587, the only station in A<sub>a</sub>, the density for every age-group is considerably below the average density for A<sub>a</sub> found in Sept. 1922, and for the II- and III-groups, the density is even as small as one fifth of the corresponding average densities in 1922, but there are for each age-group one or two stations in 1922 with a still smaller density than in 1905. Also the Station 591 in B<sub>a</sub> shows for each age-group and especially for the I- and II-groups a smaller density than the average value for B<sub>a</sub> in 1922,

<sup>1</sup> A. C. JOHANSEN 1910, Table 58 and 66.

<sup>2</sup> „ „ „ „ 1915, Fig. 25.

but again it is possible in the case of each age-group, to point to a couple of stations from 1922 which show an even smaller density than that found for Station 591. For Stations 593, 594, and 595 in C the densities are, however, not essentially smaller in 1905 than the average value for C in 1922. Regarding the total number, and also the number of plaice of the sizes 10—19 cm, we have, moreover, information from three stations from A<sub>a</sub> and A<sub>b</sub> which show a somewhat greater density than St. 587 in A<sub>a</sub>. On the whole it appears that the total density west of Graa Deep is about 3 times as great in 1922 as in 1905, and that the density of the II-group has perhaps increased by an even greater rate. But the only station in A<sub>b</sub> observed in 1905 has a somewhat greater total density than the average total density for A<sub>b</sub> in 1922.

**Table 3. Number of Plaice caught per hour by a 50 feet otter-trawl with extra cod-end in each Area. April 27.—May 10. 1907.<sup>1</sup>**

<sup>1</sup> See A. C. Johansen 1908, pp. 11—12.

In the spring of 1907 the catch per hour is even smaller than in the autumn of 1905 (see Table 3 and Fig. 3). For the I-group and perhaps also for the II-group, the smaller lengths of the fish in May may partly account for the extremely small catches per hour. At any rate there is not, for the III- and IV-groups such large differences between the values for 1907 and for 1922. The numbers in these groups are, in A<sub>a</sub> and A<sub>b</sub>, about as frequent in May 1907 as in September 1922, but in B<sub>a</sub> and B<sub>c</sub>, they are much less so in 1907 than 1922. One would expect to find in May, an accumulation of individuals belonging to these age-groups in A<sub>a</sub> and B<sub>a</sub> which vanishes during the course of the summer when the plaice again migrate to deeper waters. For this reason a better basis of comparison is perhaps obtained by considering the average density for all the areas, and for the III- and IV-groups this is about four times as great in September 1922 as in May 1907.

The general impressions obtained from a comparison of the results of the fishing experiments of 1903 to 1907 with those from September 1922 are the following:

The individuals belonging to each of the age-groups I and II are, in 1922, at least three times as numerous west of Graa Deep inside the 30 metres curve as in the earlier period, and the same is the case for the III-, IV- and V-groups as far as the data afford any information, but there is no evidence that the density outside the 30 metres curve has been greater in 1922 than in the earlier period, and on the coastal grounds north of Horns Reef the density appears to be at least as great in the autumns 1903—1905 as in 1922.

The most certain and well-founded of these results is the great increase of individuals of the I- and II-groups in the areas A<sub>a</sub> and B<sub>a</sub>. From B<sub>b</sub> no observations were taken during the years 1903—1905, and the stations examined during these years are, on the whole, so scattered that they do not give a clear picture of the regional distribution for each age-group. We therefore do not know with certainty whether the mass of each of the age-groups is to be found at the same distance from the shore in 1903—1905 and in 1922. But on the other hand the stations from A<sub>a</sub>, B<sub>a</sub> and C examined during the years 1903—1905, do not contain any indication of the maximum densities of the I- and II-groups being found outside

$B_a$ , where the maximum densities in 1922 occur. The observations of densities therefore lead to the conclusion that also the densities of the total age-groups I and II south of Horns Reef in 1922 was at least two or three times as great as during the period 1903—1905.

We shall next consider the density of the 0-group.

**Table 4. Number of Plaice in the 0-Group caught per hour by a 50 feet otter-trawl  
(with extra cod-end).**  
Autumn experiments.

Area .....	$A_a$	$A_b$
Year	Number of spec. at each station	Number of spec. at each station
1903—1905 .....	6, 37, 39, 42	30, 112, 127, 248
1922 .....	8, 39, 98, 141, 274, 590, 694	102, 130, 167, 242, 264

The frequency of the 0-group observed in September 1922 may be compared with observations from four stations from each of the areas  $A_a$  and  $A_b$  taken in the autumns 1903—1905. It will be seen from Table 4, that in  $A_a$  the 0-group is several times as large in 1922 as in 1903—1905, when the greater frequencies above 100 per hour do not occur at all. For  $A_b$  the difference is less marked. From fishing experiments with young-plaice-trawl it is known<sup>1</sup> that the 0-group as a rule is more frequent in  $A_a$  than in  $A_b$ , and the figures for 1922 are, in that respect, more normal than the other.

The experiments<sup>1</sup> with young-plaice-trawl in the summers of 1920 and 1921 indicated that the density of the 0-group at the west coast of Jutland was not unusually great as compared with the density in the pre-war years.

Thus it is only for the year 1922 that we have some evidence of a greater density of plaice fry, but the experiments with young-plaice-trawl in 1920 and 1921 are not extensive enough to warrant our excluding the possibility that the plaice fry in the North Sea was, on the whole, denser in 1920 and 1921 than usual.

The abundance of individuals of the I- and II-groups south of Horns Reef in September 1922 favours the assumption that the amount of plaice fry in 1920 and 1921 has been unusually rich as compared with pre-war years. The general change observed in the quantity and quality of the plaice population of the North Sea also supports this assumption. The stock of marketable plaice in the North Sea reached probably a post-war maximum number in 1919 as a consequence of the restriction on fishing during the War.<sup>2</sup> As the average age of the marketable plaice had also increased during the War most probably the number of spawning plaice showed a proportionately more pronounced maximum at that time, and it is probable that in 1920 and 1921 their number might still be considerably above the pre-war value.

### III. Age and length.

#### a. Average length in the different age-groups in September 1922.

The average lengths for age-groups contained in the 'Tables of Measurements A', are represented on the charts of Fig. 5. They show that in the same way as the average age and the average length of all the plaice increase from the coast seawards, so on the whole does the average length of plaice in each single year-group increase. The plaice is not only, to a certain extent, sorted naturally according to age, but the single year-groups are also sorted partly according to length. This can be noticed distinctly even in the case of the 0-group, and it is still more conspicuous in the following age-groups. But in addition to this gradation of size there are characteristic differences between the average length of an age-group south and north of Horns Reef.

<sup>1</sup> A. C. JOHANSEN 1922 p. 14.

<sup>2</sup> Compare: FR. HEINCKE 1922, H. HENKING 1922, p. 80, and J. O. BORLEY 1923, pp. 41—42.

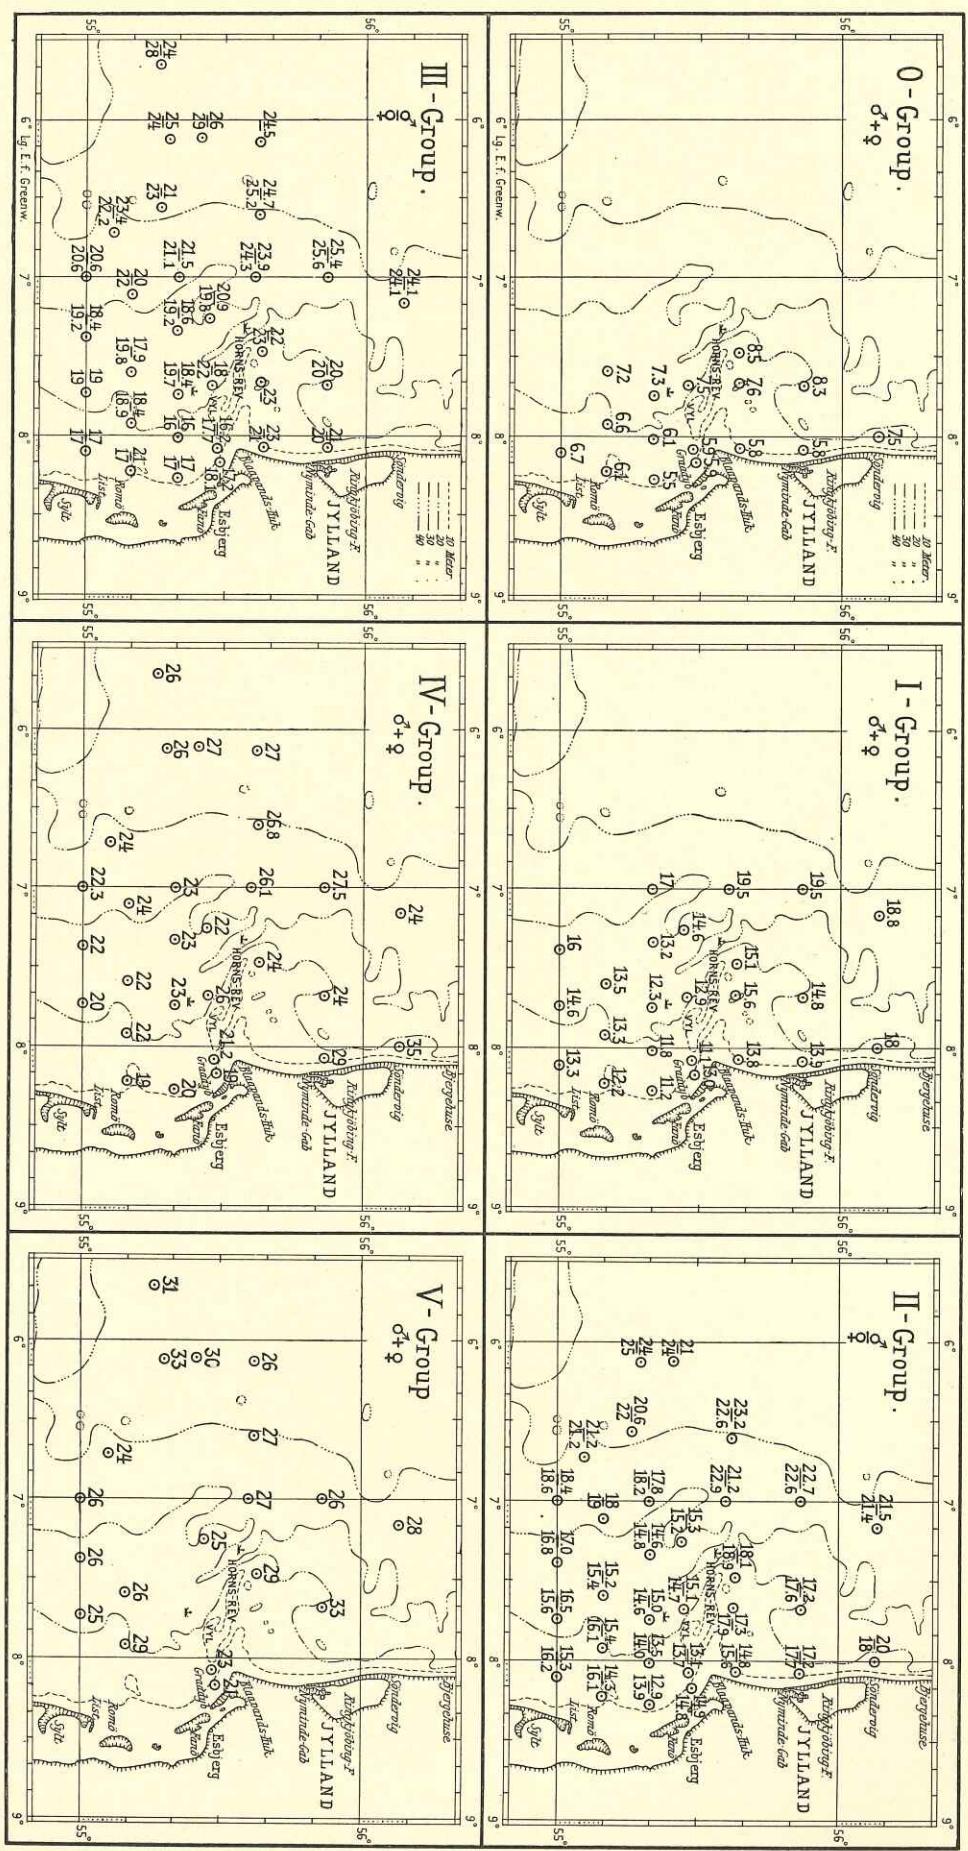

Fig. 5. Showing average lengths (cm) of plaice in the age-groups 0—V. September 1922

Table 5. Average Length in Age-Groups for each Area, September 1922.

Age-group.....	0		I		II		III		IV		V
	♂+♀	♂	♀	♂	♀	♂	♀	♂	♀

average lengths as the III-, IV-, and V-groups respectively in  $A_a$ . The average length is, however, not much larger in  $B_a$  than in  $A_a$ , especially not in the I- and II-groups. The distribution of frequencies, as well as the average lengths for these age-groups, suggests therefore that there is an active interchange of plaice between  $A_a$  and  $B_a$ , whilst the Horns Reef acts as a boundary between  $A_a$  and  $A_b$  thereby causing each of these areas to have a population with distinct characters. For the I- and II-groups it is noticed that the average length in the north to south direction has a minimum value in  $A_a$  and  $B_a$  west of Graa Deep, at that place, where for the same age-groups, a maximum of density was observed. For the III- and IV-groups such a definite minimum value of the average length can not be demonstrated and neither did there occur any maximum of density for these age-groups. On the whole, the average lengths for these age-groups decrease as one passes from north to south.

The considerable difference in length between plaice of the same age living north and south of Horns Reef is further illustrated by Table 6. It gives, for the two areas ( $A_a + B_a + B_b + C$ ) and ( $A_b + B_c$ ) and for each age-group, the distribution of lengths per 100 individuals and the average length. The table is calculated so that each station has been weighted according to the number of plaice caught per hour, and it gives therefore a complete picture of each age-group for each of the two areas, and affords the means of determining the annual growth. Assuming that the average length for each age-group is the same in 1921 as in 1922 we find from Table 6 the values for annual growth given in the following table:

Table 7. Annual Growth in centimetres.

Year of life .....	1st	2nd	3rd	4th	5th
Southern area .....	6.5	6.0	2.4	4.4	2.7
Northern area .....	6.9	8.2	4.1	4.6	2.0

It will be seen that the growth during the second and third year is decidedly larger in the northern than in the southern area.

While it is, on the whole, impossible to decide to what extent the gradation according to size from the coast seawards is produced by the larger fish having a greater disposition to emigrate than the smaller ones and to what extent by a better nourishment on the seaward grounds, it is somewhat easier to explain the reasons why the plaice of a given age are larger north than south of Horns Reef. The differences between the density and the average length for the I- as well as the II-group in the areas south and north of Horns Reef are so considerable and so sudden, as will be seen from the charts Fig. 1 and 5, that it is difficult to imagine that a frequent exchange of individuals of these age-groups occurs between  $A_a$  and  $A_b$ . The possibility that the great average lengths in  $A_b$  should arise as a result of a selective immigration of large individuals from  $A_a$  to  $A_b$  is therefore not probable, and it appears more likely that a difference in nourishment produces a difference in growth in the two areas. The extraordinarily large density observed for the I- and II-groups west of Graa Deep supports this explanation. The density of individuals belonging to these two annual groups is in  $A_a$  and in  $B_a$  6–7 times as great as in  $A_b$  and 9–10 times as great as the total density of older plaice in  $A_a$  and  $B_a$ , so that their number has an essential influence on the amount of nourishment per individual. Together with the maximum of density in  $A_a$  and  $B_a$  we found, as mentioned, for the same distance from the coast a minimum of average length for the I- and II-groups. Such a minimum is not found for the III- and IV-groups, which present a decreasing average length from north towards south, when comparing stations at the same distance from the coast. This is not astonishing because plaice of these age-groups have spread over the total area here investigated, and one may suppose that they have already performed so wide annual migrations that their state of nourishment is much less determined by the conditions of the locality where they are caught, although even for these age-groups there is a marked gradation of length from the coast seawards and from south towards north. In harmony with this view there is no essential difference of growth in the

4th and 5th year of life to be found for the two areas considered in Table 7. Outside the 20 metres curve one must expect a free interchange of plaice over three years of age to go on between the two areas, and there is no reason to suppose that the condition of nourishment is better in  $B_c$  than in  $B_b$ , where the population of plaice seems to be as dense as in  $B_c$ .

**b. Comparison between the average lengths for age-groups in 1922 and in 1905—1907.**

The only unsorted samples, examined as to otoliths, available from former years are those which were obtained in September 1905 and during Apr.—May 1907, and which were mentioned in the previous section.

<sup>1</sup> See A. C. JOHANSEN 1910, Tab. 58, 66 and 70.

In Table 8 the average lengths in the different age-groups, from the stations examined in 1905, are compared with the corresponding values for the nearest stations in 1922. It will be seen that there is no essential difference between the average length of the I-group in 1905 and 1922. The following table gives the difference in centimetres between the average length in age-groups in Sept. 1905 and Sept. 1922.

**Table 8 a.**

Age-group . . . . .	II	III	IV
Area			
$A_a$ . . . . .	5	6	7
$B_a$ . . . . .	4	5	5
C . . . . .	1	1	3

The table shows, in the age-groups II, III and IV, a very considerable difference for the stations in  $A_a$  and  $B_a$ . A comparison between the average lengths from these areas in Table 8 and the charts Fig. 5 shows that the large average lengths of the II- and III-groups in September 1905, are, in September 1922, found only in the outer-most part of  $B_b$ , and that values as large as those of the IV-group in 1905, do not occur at all in 1922 at any station inside the area ( $A_a + B_a + B_b + C$ ). Thus it is clear that, even if the young age-groups should be somewhat more concentrated to the neighbourhood of the coast in 1922 than in 1905, what might be suspected to occur together with the smaller length at each given place, this cannot affect the comparison much. We shall therefore in the following consider the differences found here as approximations to the differences between the means for the total age-groups in the area south of Horns Reef. Between the stations in C the difference is smaller, but nevertheless essential.

It has been found in previous investigations<sup>1</sup> that the growth of the 0- and I-group in the Horns

<sup>1</sup> A. C. JOHANSEN 1910, Table 52—59.

Reef area does not vary much from one year to another, and therefore even if the I-group had approximately the same average length in Sept. 1905 and Sept. 1922, we must not conclude that the growth in the other age-groups has been equal during the summers of 1905 and of 1922. On the contrary we must suppose that the very considerable difference between the average lengths of the II-groups in the two periods can be considered as a measure of the difference of growth for the age-groups II to IV in the area ( $A_a + B_a$ ) during the two summers, although the still greater differences in the III-group and in the IV-group indicate that the growth during the summer of 1904 also must have been quicker than during the summer of 1921. As the differences of lengths are so much smaller for the stations in C it is permissible to suppose that the growth in these waters has been about equal in 1904—1905 and in 1921—1922, and that it is while living in the more coastward waters that the plaice caught in C have been subjected to different environments, causing a different rate of growth.

In Table 9 the average lengths in the age-groups I, II, III, ... as found in April—May 1907, are compared with the average lengths in the age-groups 0, I, II, ... as found in September 1922 at the closest neighbouring stations. The following tables gives the average deviations in centimetres for A<sub>a</sub> and A<sub>b</sub>.

Table 9 a.

Age-group .....	I—0		II—I		III—II		IV—III		V—IV	
	1907	1922	1907	1922	1907	1922	1907	1922	1907	1922
A <sub>a</sub> .....	2	1	7	7	7	9				
A <sub>b</sub> .....	2	3	5	7	7	9				

According to the experiments of marking<sup>1</sup> 2 centimetres of these deviations must be considered as due to the growth which has taken place between the middle of September 1906 and the beginning of May 1907, but there still remains considerable deviations, which are probably not due entirely to differences in growth. There is no doubt that the larger plaice approach the coast in spring, and just at the beginning of May they are, as a rule, most frequent in the coastal waters near Horns Reef; therefore it must be excepted that at this season a higher percentage of the larger plaice of each age-group is present in A<sub>a</sub> and B<sub>a</sub> than at the end of the summer, when the larger plaice have again migrated into deeper

<sup>1</sup> A. C. JOHANSEN 1915 Fig. 25 p. 32.

waters. For this reason it is perhaps of greater interest to compare the average lengths in the spring of 1907 with the average lengths for the total age-groups in 1922 as given in Table 6. The following differences are found:

Table 9 b.

Age-group	I—0		II—I		III—II		IV—III		V—IV	
	1907	1922	1907	1922	1907	1922	1907	1922	1907	1922
A <sub>a</sub>	2		1		6		6		8	
A <sub>b</sub>		3		4		4		6		7

Even if a growth of 2 cm is admitted to take place between September and May, the age-groups II, III and IV in 1922 still shows a considerable inferiority in size.

Assuming that the difference in length between the III-group in the spring of 1907 and the II-group in September 1922, after deduction of the 2 cm mentioned above, is due substantially to difference of growth rate in (A<sub>a</sub> + A<sub>b</sub>) during the summers of 1906 and 1922, we find that the growth rate was about 3 cm higher in 1906 than in 1922, while we have found above that it was about 4.5 cm higher in 1905 than in 1922. According to the experiments of marking the growth rate in the Horns Reef area was 7.9 cm in 1905 and 6.1 cm in 1906, from which two values we find for the growth rate in 1922 for young plaice older than two years, the values 3.4 cm and 3.1 cm respectively.

For A<sub>b</sub> we find from the survey above, that the growth rate in 1906 was only 2 cm larger than in 1922, which agrees well with the fact that the extraordinarily high density of population in September 1922 does not extend to A<sub>b</sub>.

While the present measurements of length have given rather precise information about the growth rate in 1922, they afford a more uncertain basis for deducing the growth in 1921. We can only state that the growth in 1921 in all probability has been less than the growth in 1905 and in 1904, since the average lengths for the III- and IV-groups appear so small in 1922 as compared with former years. For 1920 the marking experiments from the Horns Reef area has determined the rate of growth to be ca. 7 cm (see section VI). It is therefore probable that the unusually small average lengths observed in September 1922 in the Horns Reef area are caused only by an abnormally slow rate of growth during the summers of 1922 and 1921.

A similar decrease of growth has been demonstrated on the Leman-Haaks line<sup>1</sup> during 1920 and the preceding years, by comparing the average lengths in age-groups of plaice measured in 1905—1906 and in 1920.

#### IV. Sex.

##### a. Proportion of the two sexes in September 1922.

In Table 10 the percentages of females in the catches are given for the various areas and for each age-group, except the 0-group. The table is calculated from the 'Tables of Measurements A' by adding together the individuals caught per hour at all stations and determining the percentage of females contained in the sum. In these tables the otolith- and the sex-determinations are not carried out for all individuals of a sample. For some of the specimens, the length only is determined and the determination of age and sex is reached by calculation. The calculation of the standard deviations given in Table 10 is based on the theoretical standard deviation of a determination of sex for a single individual, and in the further calculation it has been exactly taken into account whether in each individual the sex was actually determined or whether the sex-determination was the result of calculation.

<sup>1</sup> J. O. BORLEY 1923, pp. 28—29.

Table 10. The Percentage of Female Plaice (with standard deviation) in each Age-Group for Areas. Sept. 1922.

Age-Group . . . . .	I	II	III	IV	I—VII
Area	per cent $\pm$ S. D.				
A <sub>a</sub> . . . . .	46.5 $\pm$ 2.7	55.5 $\pm$ 2.0	62.0 $\pm$ 4.0	58.1 $\pm$ 6.5	52.9 $\pm$ 1.5
A <sub>b</sub> . . . . .	50.2 $\pm$ 4.6	52.6 $\pm$ 3.8	47.5 $\pm$ 10.3	..	50.9 $\pm$ 2.8
B <sub>a</sub> . . . . .	50.7 $\pm$ 3.5	48.0 $\pm$ 2.3	55.4 $\pm$ 3.0	56.9 $\pm$ 7.6	49.6 $\pm$ 1.8
B <sub>b</sub> . . . . .	..	42.7 $\pm$ 6.6	45.4 $\pm$ 4.4	51.4 $\pm$ 8.4	45.4 $\pm$ 3.2
B <sub>c</sub> . . . . .	28.5 $\pm$ 6.9	45.5 $\pm$ 2.7	50.5 $\pm$ 3.3	52.1 $\pm$ 6.1	45.4 $\pm$ 2.0
C . . . . .	..	17.2 $\pm$ 9.3	31.6 $\pm$ 7.4	31.6 $\pm$ 11.2	30.5 $\pm$ 5.2
Total Area investigated . . . . .	47.8 $\pm$ 2.0	50.8 $\pm$ 1.4	52.9 $\pm$ 1.8	52.8 $\pm$ 3.5	50.2 $\pm$ 1.0

Looking first at the southern area, consisting of A<sub>a</sub>, B<sub>a</sub>, B<sub>b</sub> and C, we notice for each of the age-groups II, III, and IV, a distinct decrease in the percentage of females from A<sub>a</sub> through B<sub>a</sub> and B<sub>b</sub> to C.

For the II-group the difference between the values for A<sub>a</sub> and B<sub>a</sub> is 7.5  $\pm$  3.0

" " " " " " " B<sub>a</sub> " C " 30.8  $\pm$  9.5

" " III-group " " " " " A<sub>a</sub> " B<sub>b</sub> " 16.5  $\pm$  5.9

" " " " " " " B<sub>a</sub> " C " 23.8  $\pm$  8.0

" " IV-group " " " " " A<sub>a</sub> " C " 26.5  $\pm$  12.9

For the I-group, the percentage of females is larger in B<sub>a</sub> than in A<sub>a</sub>, but the difference is only 4.2  $\pm$  4.4, and for all the plaice older than one year there is a marked decrease in the relative frequencies of females as one passes from the coastal grounds to C.

In the northern area consisting of A<sub>b</sub> and B<sub>c</sub>, which is less densely populated, and from which we therefore have fewer observations, it is possible for the I-group only to point out a decided decrease in the relative number of females from A<sub>b</sub> to B<sub>c</sub>. The difference here is 21.7  $\pm$  8.3. But only for the III-group the difference has the opposite sign, and it only amounts to  $\frac{1}{3}$  its standard deviation.

There is therefore no doubt that, for each of the age-groups I—IV, the relative frequency of females in the Horns Reef area on the whole decreases from the coastal waters seawards. In many cases the standard deviations of the percentages of females found at the single stations are so great that the seaward decrease of females is concealed, still the chart Fig. 6 showing the percentages of females contained in the II-group illustrates the case very well, except for the four most southern stations, for which the standard deviations are all greater than 7.

A relative decrease of females from the area A<sub>3</sub> to B<sub>4</sub> has previously been pointed out from the English investigations in 1906<sup>1</sup>, but in these an increase was observed from B<sub>4</sub> to C<sub>2</sub>. Our investigations in September 1922 cover, however, only a small part of the eastern C<sub>2</sub>, so that they are not even sufficient to demonstrate whether an increase of females is found east of the Dogger Bank.

Considering the frequencies for different age-groups in the same area, we notice an increase in the relative frequency of females with increasing age. Only three values in Table 10 (A<sub>a</sub>, IV; A<sub>b</sub>, III; B<sub>a</sub>, I) violate this rule, and they do not differ from their neighbouring values by more than 0.6 times the standard deviation of the difference. As examples of differences particularly large in proportion to their standard deviations, the following may be mentioned:

A<sub>a</sub>: II-gr.—I.gr. 9.0  $\pm$  3.4

B<sub>a</sub>: III-gr.—II.gr. 7.4  $\pm$  3.8

B<sub>c</sub>: IV.gr.—I.gr. 23.6  $\pm$  9.2

<sup>1</sup> A. T. MASTERMAN 1911, p. 44.

Also when we consider the total area investigated, we find a slightly larger relative number of females in the III- and IV-groups than in the I- and II-groups, but only the difference between the frequencies for I- and III-gr. approaches as much as twice its standard deviation.

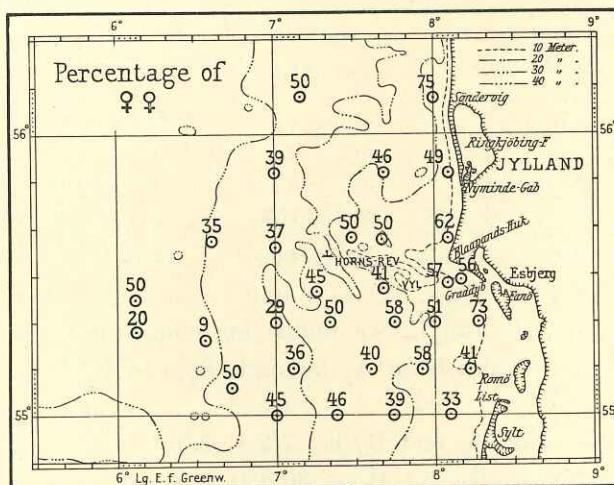

Fig. 6. Showing for the II-group the percentage of females.

passing from the coast seawards and, secondly, that, at any given place, the percentage of females of the eldest age-group found at the place, is larger than for the eldest but one, and that the percentage is always decreasing with decreasing age.

That the males should migrate further out than the females is to be expected in the age-groups which are maturing and contain a greater percentage of mature males than of mature females. But all the individuals here examined seemed immature<sup>1</sup>, and even if we could imagine that the gradation of the percentage of females for the III- and IV-groups was produced by the emigration of a surplus of mature males westwards out of the area investigated, this explanation would not hold good in the case of the II-group, of which certainly no individual has attained maturity, and which is hardly met with on deeper grounds than those investigated here. We must therefore assume that even before maturity is reached males of the young age-groups have a greater inclination, to leave the coastal grounds than females of the same age.

It will be noticed from the charts of the II- and III-groups in Fig. 5 that, comparing the average lengths of females and males of a station, the females are as a rule somewhat larger than males of the same age-group. The same impression is given by Table 5, when comparing the average length of females and males for areas. It is, however, doubtful whether in the case of these young age-groups, it is indicative

Table 11. Average Length for Males and Females south and north of Horns Reef. Sept. 1922.

Area.....	A <sub>a</sub> + B <sub>a</sub> + B <sub>b</sub> + C			A <sub>b</sub> + B <sub>c</sub>

<sup>1</sup> It is hardly possible in all cases, so early as in September, to state whether an individual will reach maturity in the approaching period of spawning or not.

of a quicker rate of growth in the females than in the males. When the larger individuals of an age-group emigrate first and when on the whole the males migrate earlier than the females, it follows, supposing equal growth for the two sexes, that at each given place the average length is greater for females than for males. Nor do we, by grouping together, in each of the two areas ( $A_a + B_a + B_b + C$ ) and ( $A_b + B_c$ ), all individuals of the same sex and the same age-group, find any superiority in the females as regards length (See Table 11).

**b. Proportion of the two sexes as found from the Danish observations in the years 1903, 1905, and 1907.**

The Tables 12 and 13 represent the relative frequencies of females as found from the previous Danish observations resulting from catches taken in otter-trawl. The standard deviations given are theoretical. A comparison of the two tables seems to show that the two sexes are represented in different proportions

**Table 12. The Proportion of Female Plaice among Individuals older than one Year.

<sup>1</sup> See A. C. Johansen 1910 Tab. 54, 60—65, and 67—68.

<sup>2</sup> See A. C. Johansen 1905 p. 8. St. 38—39, and 41.

and 1907<sup>1</sup>. In both of the tables the females, as found in September 1922, are relatively more frequent in  $A_a$  than in  $B_a$ . The observations from the years 1903, 1905 and 1907 thus show that, for all the plaice older than one year, the females decrease in relative frequency from the coast seawards, and that the females in all parts of the area investigated are in the majority in Sep-

<sup>1</sup> The English observations (mentioned on p. 17) from May—July 1906 gave for the relative frequency of females in ( $A_a + A_b$ )  $53.6 \pm 1.8$  and in ( $B_a + B_c$ )  $47.1 \pm 1.9$ . These values lie between the values here found for April—May and September.

tember whilst they are, on the whole, relatively less frequent in April—May<sup>1</sup>. This harmonises well with the fact that, in spring, there is a coastwards migration of plaice. As the relative frequency of males is greater in the deeper waters than nearer to the coast, we must expect the migration in spring to produce a rise in the percentage of males which will disappear again during the summer because of the seaward migration.

### c. Has the relative frequency of the sexes altered?

Comparing now the Tables 12 and 13 with Table 10 we notice that the percentage of females from the spring of 1903 and of 1907 agrees approximately with that found in September 1922, and that the percentage of females observed in September 1903 and 1905 shows the following deviations from the values for September 1922:

$A_a$	$A_b$	$B_a$	C
$12 \pm 3$	$11 \pm 3$	$8 \pm 2$	$26 \pm 6$

Hence these observations from the Horns Reef area point towards the assumption that the relative frequency of the two sexes has altered in such a way that the females, which among individuals older than one year were, in September 1903 and 1905, in a considerable majority, are, in September 1922, in a decided majority in  $A_a$  only, and in a distinct minority in  $B_c$  and C. The plaice considered belong particularly to the age-groups I—IV.

German observations of plaice from the south-eastern North Sea also point to a decreased relative frequency of females after the War, as mentioned by HENKING<sup>2</sup> in a recent paper. The following table has been calculated from the tables of observations<sup>3</sup> published in that paper.

Table 14. Percentage of Females among Plaice caught by German Vessels in Area B<sub>4</sub>.

Year .....	1909		1919	
	Percentage	Total number examined	Percentage	Total number examined
Total year .....	55.8	137,018	33.5	70,907
April—May .....	50.5	32,585	31.6	22,501
Sept.—Oct.....	53.6	15,951	44.4	4,155

The difference between the percentages for 1909 and 1919 is very marked especially for the spring. We further notice that the females are relatively more frequent in the autumn than in the spring, as found from Danish investigations under b of this section. This supports the assumption that the observation of an equal relative frequency of females in the springs of 1903 and 1907 and in September of 1922 may agree with a general relative decrease of females.

From the lengths of the plaice<sup>4</sup> it may be seen that the plaice from 1919 hardly contain any specimens of the I- and II-groups and that in several months, among the first six of the year, they include

<sup>1</sup> But the nature of a sample taken on 5th of May 1923 near St. 2815 warns us not to be too sure about a different sex distribution for spring and autumn. The sample caught consisted of 10092 individuals, of which 1200 specimens of lengths from about 20—28 cm were selected for special use. Amongst the remainder, 4692 specimens taken at random were measured, and the sex determined of those larger than 10 cm. They were 1864 males and 2527 females. The percentage of females among these is accordingly  $57.5 \pm 0.7$ , which is the same as that found for St. 2815 in September 1922, although in all probability we have, by omitting the larger individuals, lowered the percentage of females rather than raised it. This sample therefore gave no indication of a smaller relative frequency of females in May, but we must attach less importance to this single sample than to the result obtained from Tables 12 and 13, in which the figures for the various samples support each other.

<sup>2</sup> H. HENKING 1922, p. 83.

<sup>3</sup> I. c. Tab. 3—4.

<sup>4</sup> Compare I. c. Table 3—4.

a considerable percentage of older plaice of more than 40 centimetres in length. Just during these months the percentage of females is particularly small, from which we infer that the increased percentage of males is found at least as much among the older as among the younger age-groups.

English investigations of plaice from the southern North Sea carried out during the years 1920 and 1921<sup>1</sup> also bear evidence of an increased percentage of males as compared with pre-war values especially in the V-group and older age-groups.

Thus we have found evidence of an increased percentage of males from three different groups of post-war observations. For the Horns Reef area the increase seems to occur already in the II-group<sup>2</sup> in September 1922, but in the English and German materials the evidence of increase is clearest for the older age-groups.

It is difficult to imagine a single explanation which may be valid for all the age-groups from the II-group upwards, but we shall discuss various possibilities.

Before the War there was obviously in the total stock of the North Sea a distinct decrease in the percentage of male plaice, when passing from the age-group in which the majority of males become mature to older age-groups, but whether this greater mortality of males than of females was due to fishery or to 'natural' causes has not been fully demonstrated.

It has been pointed out by HEFFORD<sup>3</sup> that on the spawning grounds, where the males are accustomed to gather in large shoals during the spawning seasons and stay for several weeks, whereas the females occur more scattered and remain for a shorter time only, the males are much more affected by fishery than the females, and Hefford is therefore inclined to ascribe the sharp decline of mature males to a high intensity of fishing in the spawning season.

Let us consider this possibility that the fishery before the War was carried on in such a way that the mature males were more persecuted than females of the same age. If this be so, the restricted fishing during the war, even if it had taken place on the same grounds as formerly, would tend to diminish the difference of frequencies between mature males and females. As actually the fishing was particularly restricted on the spawning grounds of the southern and south-eastern North Sea, because of the mining fields, this tendency would be so much stronger.

Thus it is in good agreement with the above theory of HEFFORD that the males from the age at which the majority of males become mature should be relatively more frequent after than before the War. But this theory does not explain why the males of less than five years should in post-war years be relatively more frequent than before the War, and this is what the Danish observations in the Horns Reef area appear to show.

It was demonstrated under 'a' of this section that there was in September 1922 a decreasing percentage of females in each age-group, when passing from the cost seawards, and this was explained by supposing that the males migrated earlier than the females. As the plaice at a given age are now on an average smaller than formerly and as maturity in all probability is reached later<sup>4</sup>, it is to be expected that the segregation of males and females does also occur at a higher age now than formerly. If this be so, the relative decrease of females in the Horns Reef grounds found in September 1922, as compared with

<sup>1</sup> J. O. BORLEY 1923, Table 31.

<sup>2</sup> Compare Table 10 with A. C. JOHANSEN 1910, Tab. 58, 66, and 70.

<sup>3</sup> A. E. HEFFORD 1916, p. 39.

<sup>4</sup> Although it is not possible in September to decide with certainty whether an individual will become mature in the next spawning-period, the judgments made about maturity are valuable when compared with observations made at the same season. In September 1905 the following percentages of male individuals from the Horns Reef area were indicated as being mature:

II-group	III-group	IV-group	V-group	
14 ± 3	11 ± 3	23 ± 6	56 ± 18	} calculated from Tables 57, 58, 66, and 70 of A. C. JOHANSEN 1910.

When in September 1922, all males were judged to be immature, there is not much doubt that maturity is now attained at a higher age than formerly.

September 1903 and 1905, can be explained naturally by a different local distribution of males and females in the two periods, and there is no basis for assuming a different relative frequency of males and females in the total age-groups.

## V. Investigations of marketable plaice landed in Esbjerg.

During the period from Sept. 23rd to November 10th of 1922 measurements of 247 samples of marketable plaice landed in Esbjerg were carried out, and the measurements are recorded in Table of Measurements B. The size limit for sale in Denmark is 25.7 cm for the total length. For plaice landed for export the size-limit was from Oct. 1. 22.5 cm and in September 24.0 cm. Plaice under these sizes are therefore thrown overboard directly after the capture, but otherwise the catches sampled are not sorted for sale.

More than half of the samples are taken from catches arising from the area B<sub>4</sub>, and moreover these catches are all from the part of B<sub>4</sub> situated north of Horns Reef, which we have named B<sub>c</sub>. These samples contain on an average 110 individuals. Samples from C<sub>2</sub>, B<sub>1</sub> and D<sub>2</sub>, where the plaice were larger and less numerous, contain only 30—40 plaice. The total number of plaice measured is 23,299.

### a. Frequencies of lengths in the areas B<sub>4</sub> and B<sub>5</sub>.

In Table 15 a survey is given of the frequency distribution, according to length, per 1000 plaice

Table 16. Number of Individuals under 27 cm in length among 1000 Plaice landed in Esbjerg.

from each of the international areas fished. By comparing the figures for B<sub>4</sub> in this table with measurements undertaken in the autumn of 1905<sup>1</sup> and in August and September<sup>2</sup> of 1919 it is seen at a glance, that the samples from 1922 contain proportionately many more small plaice than the other samples. In Table 16 the number of plaice under 27 cm per 1000 individuals are given, and it will be seen that, although the fishing in 1922 took place generally on deeper grounds and north of Horns Reef, the catches contain about double the number of these small fish as compared with the samples considered from 1904—1905 and 1919. However when these samples were taken, the size limit was 24—26, and the bulk of the samples from 1922 were taken after October when the size-limit for export was only 22.5. Although we do not notice any decrease in the average length of the plaice from September to October 1922, there is the possibility that, on the whole, the sorting has altered together with the size-limit. We shall therefore compare the distribution of length for plaice over 27 cm, which cannot be essentially affected by the difference of size-limit. Table 17 gives the numerical distribution of such fish among three length-groups for the areas B<sub>4</sub> and B<sub>5</sub>. The frequencies per 1000 have first been calculated for each sample, and then the average has been found for the group of samples in question, by which proceeding we have been able to determine the empirical St. D given in the table.

Table 17. Distribution of 1000 Plaice over 27 cm among three length groups. (From landings in Esbjerg).

under 30 cm .....	593 ± 37	604 ± 18	580 ± 22	829 ± 7	758 ± 30	784 ± 27
between 30 and 33 cm .....	287 ± 26	263 ± 11	286 ± 11	147 ± 6	201 ± 24	171 ± 17
over 33 cm .....	120 ± 17	133 ± 12	133 ± 15	25 ± 3	41 ± 11	55 ± 11

It will be seen from the table, that the samples from B<sub>4</sub> and B<sub>5</sub> taken in 1922 show approximately the same distribution, those from B<sub>5</sub> being only somewhat more abundant in plaice over 33 cm. The distribution found for 1922 does not deviate essentially from that found for the samples from B<sub>5</sub> in 1904—1905. But the samples from B<sub>4</sub> taken in 1904—1905 and 1919 contain a considerably greater percentage of plaice larger than 30 cm. Now it was found previously<sup>3</sup> that quite extraordinary catches in September of 1905 were landed from B<sub>4</sub>, which, as compared with the ordinary catches at that time and from that

region, consisted of unusually large fish. Among the 24 samples of the first column of Table 17, 8 have arisen from such catches and the remaining 16 samples give the following percentages:

Under 30 cm.....	69.4
Between 30 and 33 cm.....	22.1
Over 33 cm.....	8.5

It will be noticed that each percentage value lies between the corresponding percentages for 1919 and for 1922.

We arrive therefore at the following conclusion: The measurements of marketable plaice from B<sub>4</sub> prove that the percentage of plaice over 30 cm, contained in the stock of plaice over 27 cm in October 1922, is considerably below that found in August and September 1919 and also smaller than in September to November 1904—1905. From B<sub>5</sub> we also find a higher percentage in 1922 of plaice smaller than 27 cm than in 1904—1905, but this may be due to different sorting, since for plaice larger than 27 cm the distribution among size-groups is essentially the same during these two periods of sampling.

#### b. Frequencies of lengths in the areas C<sub>2</sub>, B<sub>1</sub>, and D<sub>2</sub>.

The samples of plaice from the areas B<sub>1</sub> and D<sub>2</sub> are not at all, and those from C<sub>2</sub> very little, influenced by sorting, and can therefore be compared directly with samples taken when the size-limit was different from that in October 1922.

A study of the samples from C<sub>2</sub> in the "Table of Measurements B", shows that the distribution of

length and the average length of the samples differ considerably according to whether the fishing-place is situated in the areas  $L_9$ ,  $K_9$ , and  $K_{10}$ , i. e. east of the Dogger Bank, which we shall name  $C_2, e$ , or in the areas  $G_{10}$ ,  $H_{10}$ ,  $K_{11}$ , and  $K_{12}$ , i. e. northwest and north of the northeastern part of the bank, which we shall designate  $C_2, n. w.$ . In the latter areas the plaice are much larger than in the former and also larger than in the part of the Dogger Bank sampled in 1922, i. e. the northeastern part of the bank. Because the Danish measurements of plaice previously carried out in  $C_2$  deal only with samples from  $C_2, e$  we shall, in Table 18, consider the two parts of  $C_2$  separately and compare with the previous measurements taken in 1916<sup>1</sup> and 1919<sup>2</sup>.

When comparing the separate samples from the periods of measurements in 1916 and 1919, no seasonal variation in the length of the plaice can be traced during July—Sept., so we may regard them as suitable for comparison with the samples from 1922, of which nine have been taken in September. The table therefore shows that the great relative frequency of large plaice over 35—40 cm observed in 1919, as compared with 1916, has entirely vanished from  $C_2, e$  in 1922, when the smaller sizes of plaice are on the contrary proportionately more frequent than in 1916.

**Table 19. Average Length of Plaice with empiric Standard Deviations. (From landings in Esbjerg).**

Area.....	$C_2, e$			$B_1$	$C_2, n. w.$
	July—Sept. 1916	July—Sept. 1919	Sept.—Oct. 1922		
Period of sampling .....				Oct.—Nov. 1922	Oct. 1922
Number of samples .....	26	16	10	20	8
Average length .....	$33.0 \pm 0.4$	$39.8 \pm 1.2$	$29.8 \pm 0.3$	$44.0 \pm 1.1$	$46.5 \pm 1.0$

From Table 19, in which the average length is calculated as the mean value of the average length found for each sample equally weighted, and in which the standard deviation is calculated from the empiric standard deviation for means of samples, we gain some idea of the reliability of the results. It will be noticed that there is a systematic difference between the average lengths given in Tables 18 and 19, owing to the different principle of calculation. The means of Table 18 are the average values for all plaice measured from an area, while those of Table 19 are the average values for means of sample of approximately equal weight. It follows from this, that the samples with greater average length contain a smaller number of individuals, and therefore the averages of Table 19, where the same weight is given to each sample, must be greater than the corresponding averages of Table 18 calculated for the whole collection of individuals from one area. The difference between the two average values is approximately the same for each group of samples, and the St. D.'s given in Table 19 show that the differences between the average lengths in  $C_2, e$  in 1916, 1919, and 1922 are all significant.

It is, however, further seen from Table 19 that moving from area  $C_2, e$  in north-westerly direction we find in the neighbouring areas  $B_1$  and  $C_2, n. w.$  in 1922 plaice the average length of which is decidedly above even that found for  $C_2, e$  in 1919, the deviations from this value being  $4.2 \pm 1.6$  and  $6.7 \pm 1.5$  respectively. It is therefore possible that the decrease of average length observed in  $C_2, e$  is partly due to a different local distribution of the plaice in the autumn of 1922 as compared with the periods of observation in 1919 and 1916.

### c. Frequency of lengths in the area $A_3$ .

The samples from  $A_3$  contain a still greater percentage of small plaice than those from  $B_4$ . (See Table 15). We have, for comparison, no samples taken in the month of October in previous years, but

<sup>1</sup> JOHANSEN and SMITH 1919, pp. 32—33.

<sup>2</sup> SMITH 1921, pp. 46—47.

compared with samples taken in September of the years 1904—1905 and 1919<sup>1</sup> we again find that the samples from Oct.—Nov. 1922 consist of unusually small fish, the number of plaice under 27 cm being 783, whereas it was only 440 and 309 respectively during the periods of sampling mentioned. This might perhaps be due partly to the small size-limit in force, and we must examine the distribution according

Table 20. Distribution of 100 Plaice over 27 cm in length according to length.  
Area A<sub>3</sub>. (Landings in Esbjerg).

Period of sampling . . . . .	Sept. 1904—1905	Sept. 1919	Oct.—Nov. 1922

over 33 . . . . .	4 ± 4	19 ± 1	0.7 ± 0.4

to length of the plaice over 27 cm. Table 20 represents the distributions of 100 plaice over 27 cm. It will be seen that there is a distinct difference between 1919 and 1922 in the distribution of the plaice over 27 cm, the sizes 27—29 cm being abundantly represented in 1922 as compared with 1919; on the other hand, plaice over 33 cm amounted in 1919 to 19 per cent against only 0.7 per cent in 1922. Compared with the samples from 1904—1905, those from 1922 contain a greater percentage of the length 27 cm and a smaller percentage of the lengths over 29, but the differences are less pronounced.

Thus for both of the areas B<sub>4</sub> and A<sub>3</sub> we have found that, comparing plaice over 27 cm, the frequency distribution of which can be considered independent of the different size-limits, the size-group over 30 cm in 1922 represents a much smaller percentage of the total number than in 1919 and a somewhat smaller percentage than in 1904—1905. When it is so, it is probable that the relative abundance of plaice under 27 cm found in 1922 is not due solely to the smaller size-limit in force, but is a sign of a greater relative frequency of this size-group in the unsorted catches.

#### d. Age of the marketable plaice in B<sub>c</sub> in the autumn of 1922.

We shall make an attempt at calculating, by means of the fishing experiments undertaken in September 1922, the age-composition of the marketable plaice from B<sub>c</sub> captured in the autumn of 1922. Starting with the sum of plaice caught per hour at each of the stations in B<sub>c</sub> we assume that plaice over 27 cm are unaffected by sorting, and that the frequencies for size-groups under 27 cm have been reduced so much that their proportion to the total number over 27 cm is the same as that found for B<sub>4</sub> in Table 15. We thus arrive at the distribution given in Table 21. It will be seen that 53% of the market plaice belong to the III-group, 22% to the II-group, 21% to the IV-group, and the remaining 4% to the V-group. When the marketable plaice are so young it is clear that their average length and, on the whole, their distribution according to length, depends very much upon the growth rate during the last two periods of growth.

For the spring of 1922 we have a sample of marketable plaice from the deeper part of B<sub>a</sub>, examined as to otoliths (Table 22). About half of the plaice are four years old, about one fifth three years, and as many five years. They are of about the same age as the marketable plaice found in B<sub>a</sub> and B<sub>b</sub> in

<sup>1</sup> See K. SMITH 1921, Table 9 and Table 10 pp. 13—14.

<sup>2</sup> One of these mature.

<sup>3</sup> Not corrected by 0.5.

1919<sup>1</sup> and of 1920<sup>2</sup>, we find that it is, on an average, about 1.1 year younger than these. In Sept. 1922 the marketable plaice from A<sub>a</sub> is according to Table 23 only 0.5 year older than those from B<sub>a</sub> so that we are justified in assuming that the average age of the marketable stock of plaice in the Horns Reef area has decreased after the fishing had been carried on more or less normally for the years following the War.

Accordingly we find two causes why the marketable plaice from B<sub>4</sub> in 1922, as com-

<sup>1</sup> A. C. JOHANSEN and K. SMITH 1919, p. 23.

<sup>2</sup> K. SMITH 1921, pp. 22—23

pared with 1919, should be smaller: (1) the percentage of the older age-groups contained among the market plaice has diminished as a result of a more normal intensity of fishing after the War, (2) the growth rate has, in 1922, and probably in 1921, been unusually small, so that the length of marketable plaice from each given age-group is smaller presumably than in 1919. The last cause may explain why the market plaice in 1922 were smaller than in 1904—1905.

#### e. Density of marketable plaice in the autumn of 1922.

To get an idea of the density and the age of marketable plaice in the various areas with which we have worked in Sections II—IV, we shall consider the number of plaice over 24 cm caught per hour in the fishing experiments of September 1922 (see Table 23). From 1. Oct. it is permitted to land plaice over 22.5 in total length, but only a few of the lengths 22 and 23 cm are actually landed, as will be seen

**Table 23. Number of Plaice over 24 cm Caught per hour by a 50 feet otter-trawl.  
September 1922.**  
(Calculated from the fishing experiments).

Age-group .....	II	III	IV	V	VI	Total	Average age on 1. April 1922
Area							
A <sub>a</sub> .....	0.0	0.1	0.9	0.6	0.0	1.6	4.3
A <sub>b</sub> .....	1.0	1.0	0.6	0.4	0.0	3.0	3.1
B <sub>a</sub> .....	0.0	2.6	2.1	1.0	0.1	5.9	3.8
B <sub>b</sub> .....	0.6	7.7	4.4	2.1	0.3	15.1	3.6
B <sub>c</sub> .....	11.1	29.2	12.1	2.1	0.0	54.6	3.1
C .....	0.5	2.4	1.8	0.8	0.2	5.7	3.6

from Table 15. Nor are plaice of 24 cm fully represented in the landings, but by entirely neglecting the plaice under 24 cm, and by counting all the individuals of 24 cm from the fishing experiments, we get a fair approximation to the distribution of marketable plaice among age-groups. It will also be seen that the distribution among age-groups of plaice over 24 cm from B<sub>c</sub>, as given in Table 23, agrees pretty well with the distribution of marketable plaice in Table 21 found by the more elaborate method described above.

It appears from Table 23 that the density of marketable plaice in September was extraordinarily great in B<sub>c</sub>, the part of B<sub>4</sub> situated north of Horns Reef, the density being 3—4 times as great as in B<sub>b</sub> and about 10 times as great as in B<sub>a</sub> and in C. The distribution of the marketable samples among the areas (see Table 15), which is approximately indicative of the catches obtained, shows that this comparative abundance in B<sub>c</sub> has continued also throughout the month of October.

Comparing Table 23 with Table 1 it will further be seen that this relative abundance of marketable plaice in B<sub>c</sub> is chiefly due to the better growth. Comparing in Table 1 the frequencies of an age-group for different areas, in no case do we find the maximum value in the area B<sub>c</sub>, but the ratio of marketable plaice in each of the age-groups II—IV to the total number of plaice in an age-group is much greater in B<sub>c</sub> than in B<sub>a</sub> and B<sub>b</sub>, and is only excelled by the corresponding ratios in C. The III-group, which in the areas B<sub>a</sub>, B<sub>b</sub> and B<sub>c</sub> is the basis of the marketable plaice, is about as frequently represented in B<sub>a</sub> and B<sub>b</sub> as in B<sub>c</sub>, but nevertheless the density of marketable plaice belonging to the III-group is in B<sub>a</sub> only about one eleventh and in B<sub>b</sub> about one fourth of that in B<sub>c</sub>. The II-group, which in B<sub>c</sub> contributes essentially to the marketable plaice, is of absolutely no value to the fishery in the areas A<sub>a</sub> and B<sub>a</sub>, where it is about three times as dense as in B<sub>c</sub>.

## VI. Marking experiments in the spring of the years 1920 and 1921.

The plaice were marked with a label consisting of a bone button and a brass disc connected by means of a silver wire. The bone button carries another brass disc, in which a number is stamped.

In Fig. 7—13 illustrating the results of the experiments the places of liberation are denoted by a small circle and the places of recapture by a spot for females and an arrow head for males. The two places are connected by a straight line or a curve. The figure near the place of recapture indicates the number of calendar months initiated between liberation and recapture. The nationality of the vessel by which the plaice has been recaptured is denoted at the place of recapture by putting Da for Danish, E for English, G for German, H for Dutch and Sc for Scottish. Nearly all the plaice have been recaptured by Danish vessels, and the indication 'Da' is therefore omitted except in Fig. 10, which represents the widest migrations.

### a. Migrations of marked plaice.

*Marking experiment No. 1* (Fig. 7). On the 23rd of April 1920 50 plaice were liberated outside the Graa Deep bar, at  $55^{\circ} 26'$  N. Lat.,  $8^{\circ} 15'$  E. Long. (Depth: 12 m).

*Marking experiment No. 2* (Fig. 7). On 23rd of April 1920 110 plaice were liberated west of Fanø, at  $55^{\circ} 25'$  N. Lat.,  $8^{\circ} 16'$  E. Long. (Depth: 10 m).

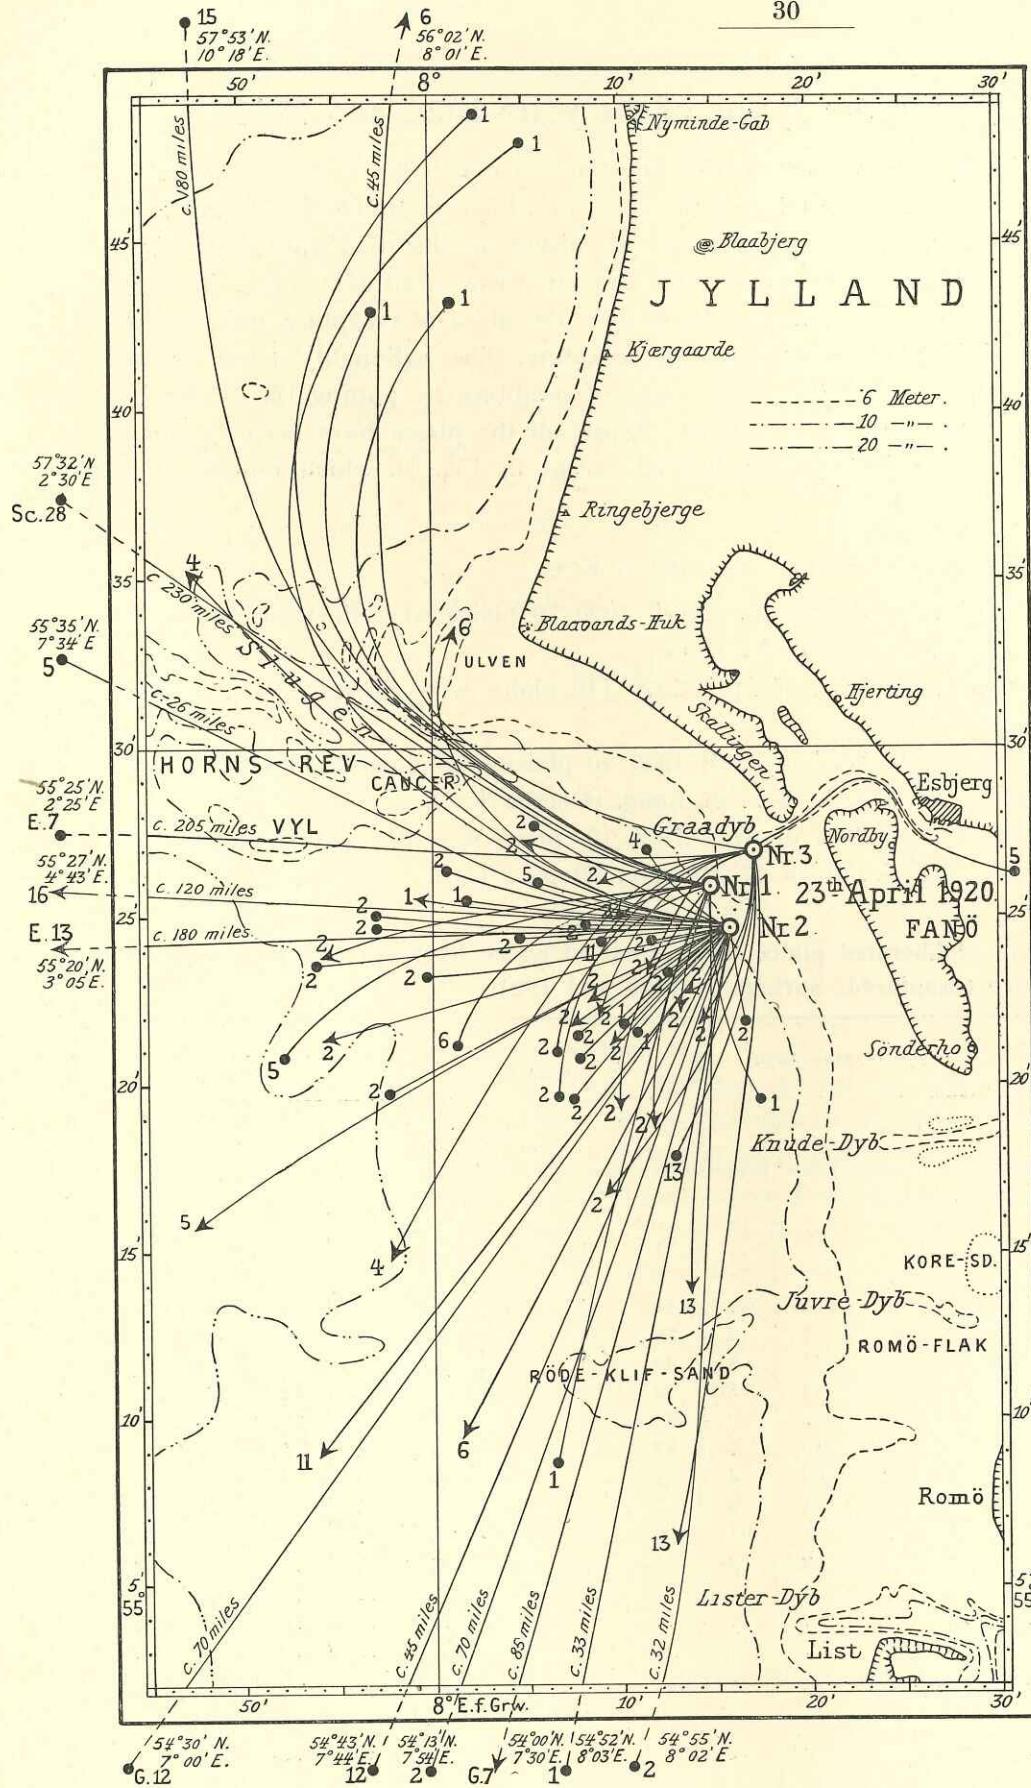

*Marking experiment No. 3* (Fig. 7). On 23rd of April 1920 40 plaice were liberated inside the Graa Deep bar, W. by S. of "Bjælken", at  $55^{\circ} 27'$  N. Lat.,  $8^{\circ} 17'$  E. Long. (Depth: 4 m).

*Marking experiment No. 4* (Fig. 8). On 23rd of April 1920 100 plaice were liberated inside the Graa Deep bar, W. by N. of "Bjælken" at  $55^{\circ} 27'$  N. Lat.,  $8^{\circ} 17'$  E. Long. (Depth: 4 m).

<sup>1</sup> Not corrected by 0.5.

In these four marking experiments of 23rd of April 1920, which all took place west of the northern end of the island of Fanø, a total of 300 plaice (133 ♂♂ and 167 ♀♀) were liberated. Before the end of May only 16 specimens (1 ♂ and 15 ♀♀) were recovered; they were all caught in the area A<sub>3</sub>, but as seen from the charts (Fig. 7 and 8) at essential greater depths than those of the places of liberation; 10 were caught south of Horns Reef and 5 north of the reef. During June 69 specimens (28 ♂♂ and 41 ♀♀) were recaptured, one north of Horns Reef in B<sub>5</sub>, one south of Horns Reef in B<sub>4</sub>, one near Helgoland, and the remaining 66 in A<sub>3</sub> south-west of the places of liberation. During July only one specimen was caught (in A<sub>3</sub>). During August 10 plaice were recovered, 5 in A<sub>3</sub> and 5 further seaward; during September 8 plaice, of which 3 were caught at greater depths than 20 m and one between Jutland and Fanø. During October only 4 specimens were recaptured and 3 of these in A<sub>3</sub>; during November 2 specimens, one in A<sub>3</sub> and one in C<sub>2</sub>. In the following two months no recaptures occurred, but during the months February to May inclusive of 1921, 10 specimens (average growth: 6.3 cm) were caught on the Horns Reef grounds between the reef and 54° 30' N. Lat., and besides these, a male of 29.5 cm (growth: 5 cm) on the Dogger Bank, and a male of 32 cm (growth: 3 cm) in the central part of B<sub>3</sub>. During July 1921 a female of 34 cm (growth: 10 cm) was recovered near Hirts-

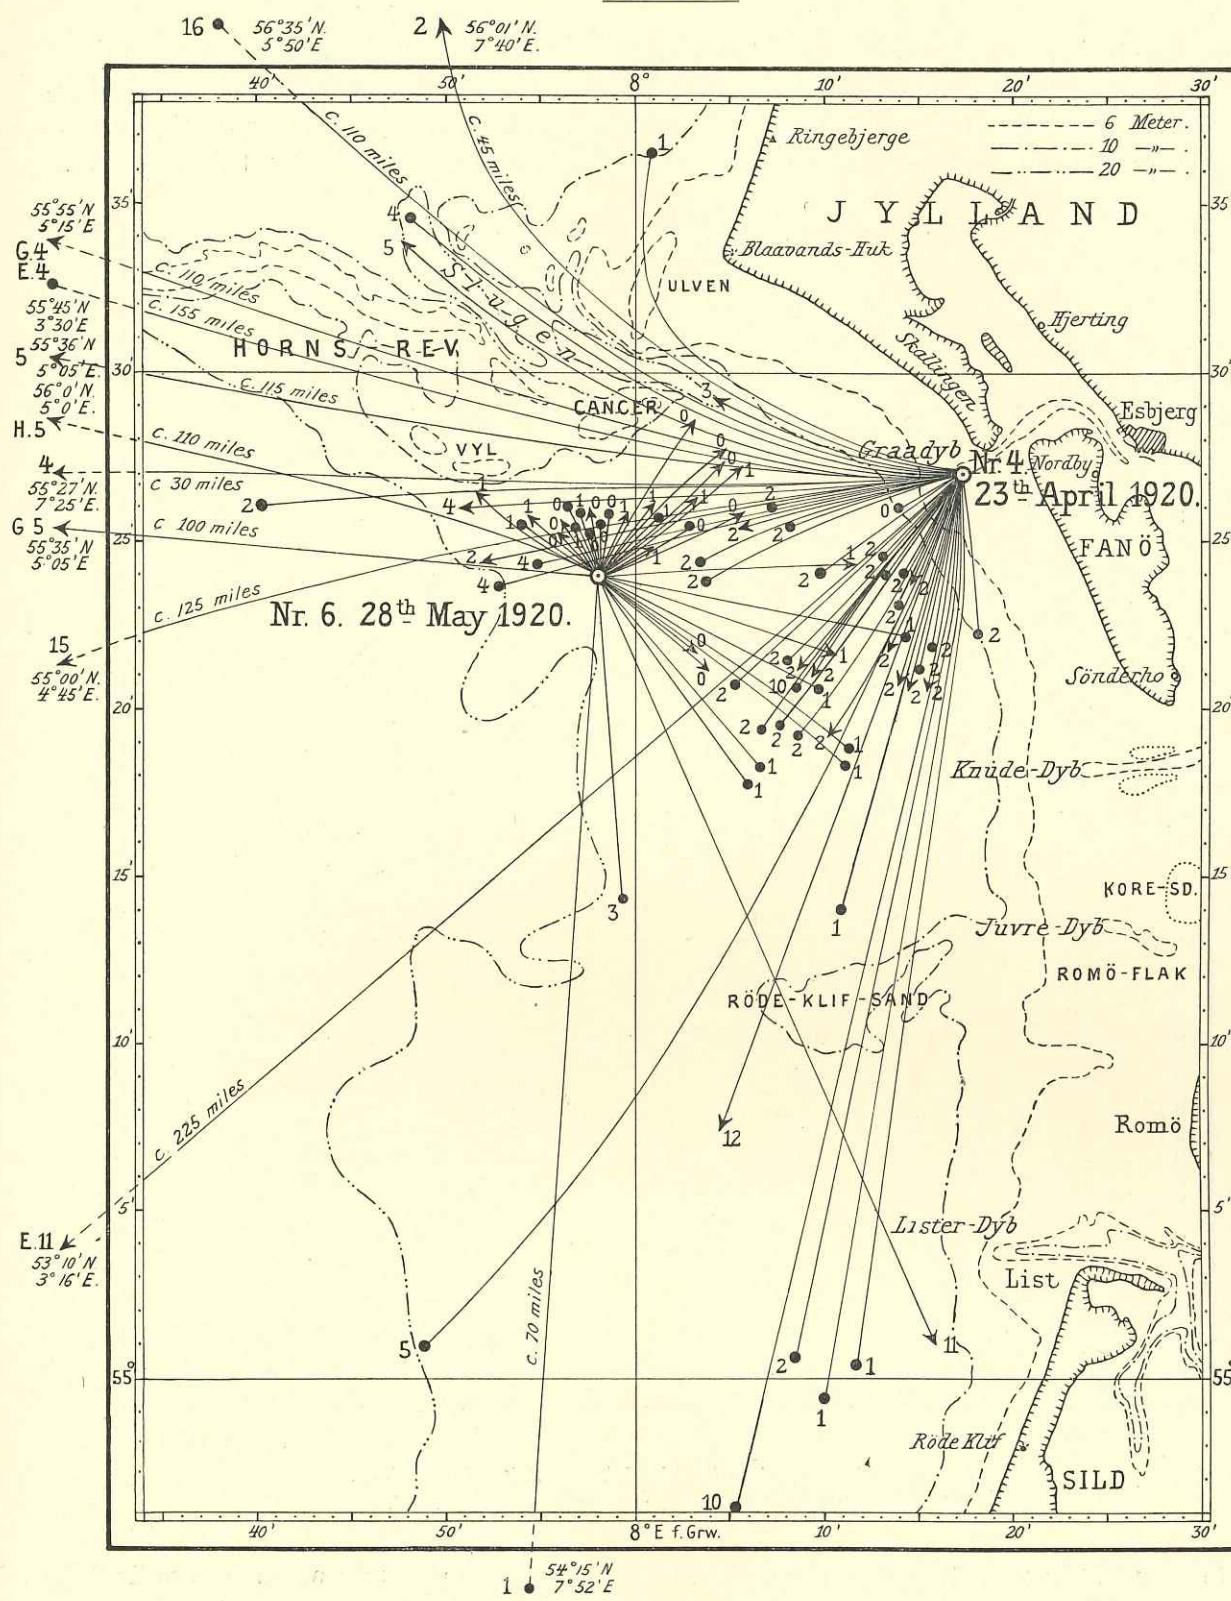

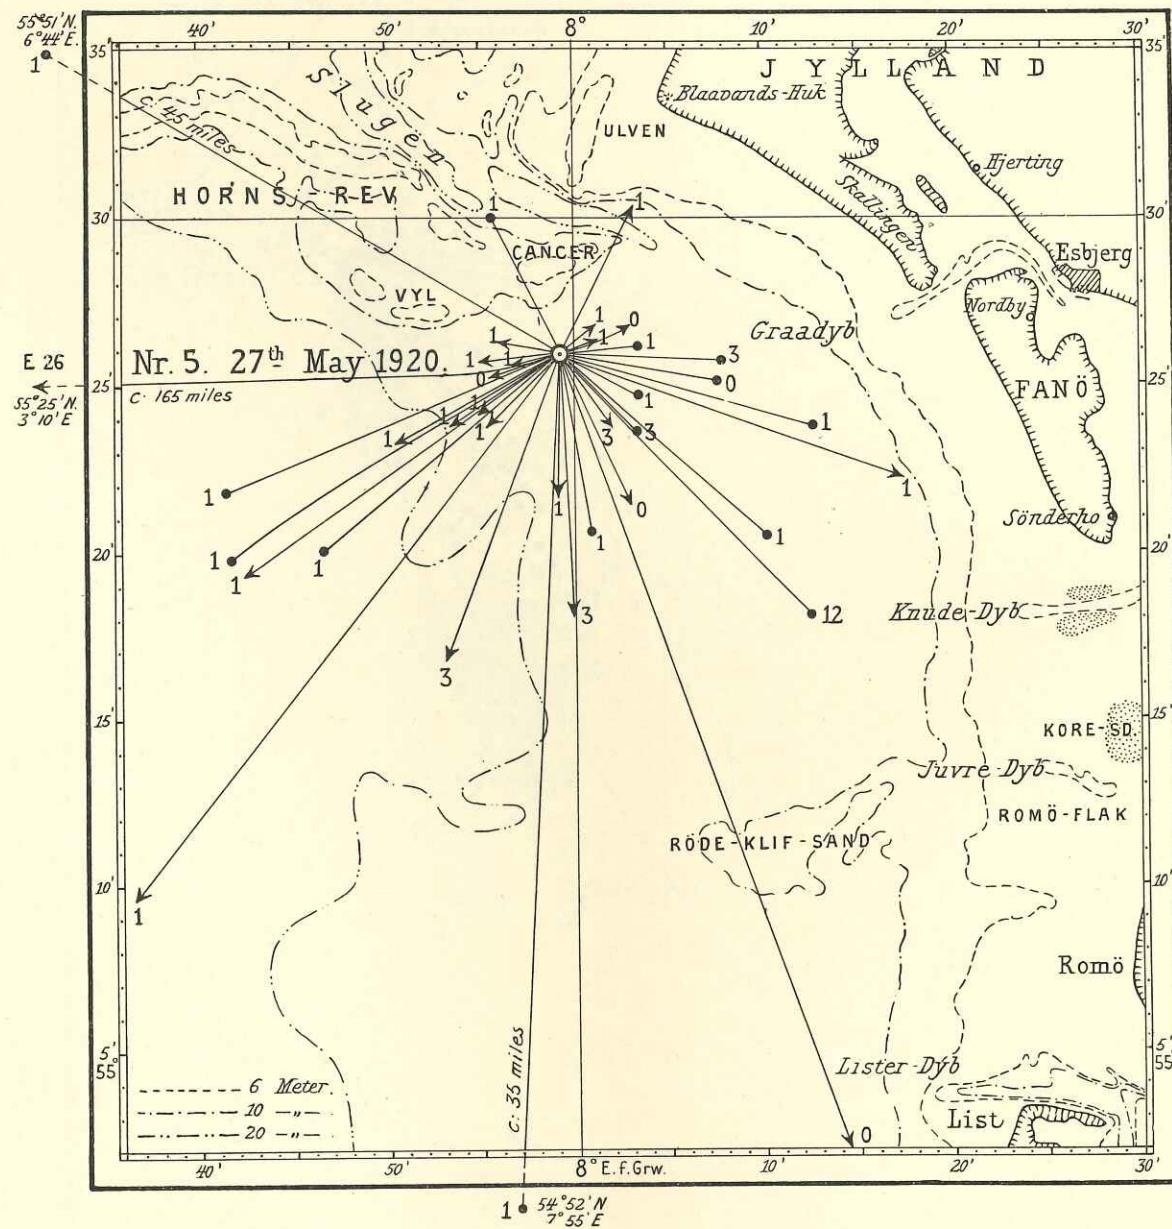

Fig. 8. Marking experiments with plaice in the spring of 1920.  
Females denoted by a spot, males by an arrow head.

hals and a male of 35 cm (growth: 7 cm) in C<sub>2</sub> east of the Dogger Bank. During August a male of 28 cm (growth: 6 cm) was caught on the Dogger Bank, and a female of 42 cm (growth: 17 cm) north-east of

the north-eastern end of that bank. Between that date and 1st of Oct. 1923 only one more specimen was recovered viz. a female of 42 cm (growth: 15 cm) caught in August 1922 in the western part of D<sub>2</sub>.

It will be seen from this account that the positions of the places of recapture during June, July, and August 1920 confirm the previous evidence of an off-coast migration during the summer. During

February to May of the year 1921, nearly all the recaptures occur once more on the Horns Reef grounds and thus indicate that an essential portion of the marked plaice are again present on the coastal grounds.

*Marking experiment No. 5* (Fig. 9). On 27th of May 1920 100 plaice were liberated south of Horns Reef at 55° 26' N. Lat., 7° 59' E. Long. (Depth: 15 m).

*Marking experiment No. 6* (Fig. 8). On 28th of May 1920 100 plaice were liberated south of Horns Reef, at 55° 24' N. Lat., 7° 58' E. Long. (Depth: 15.5 m).

Of the 200 plaice (112 ♂♂ and 88 ♀♀) liberated in these two experiments of 27th and 28th of May 1920 66 (37 ♂♂ and 29 ♀♀) were recaptured before the end of June. The positions of the places of recapture, as seen from the charts, indicate a general spreading of the plaice, and the depths of the places of recapture do not indicate a marked migration towards greater depths, the average of the 64 depths

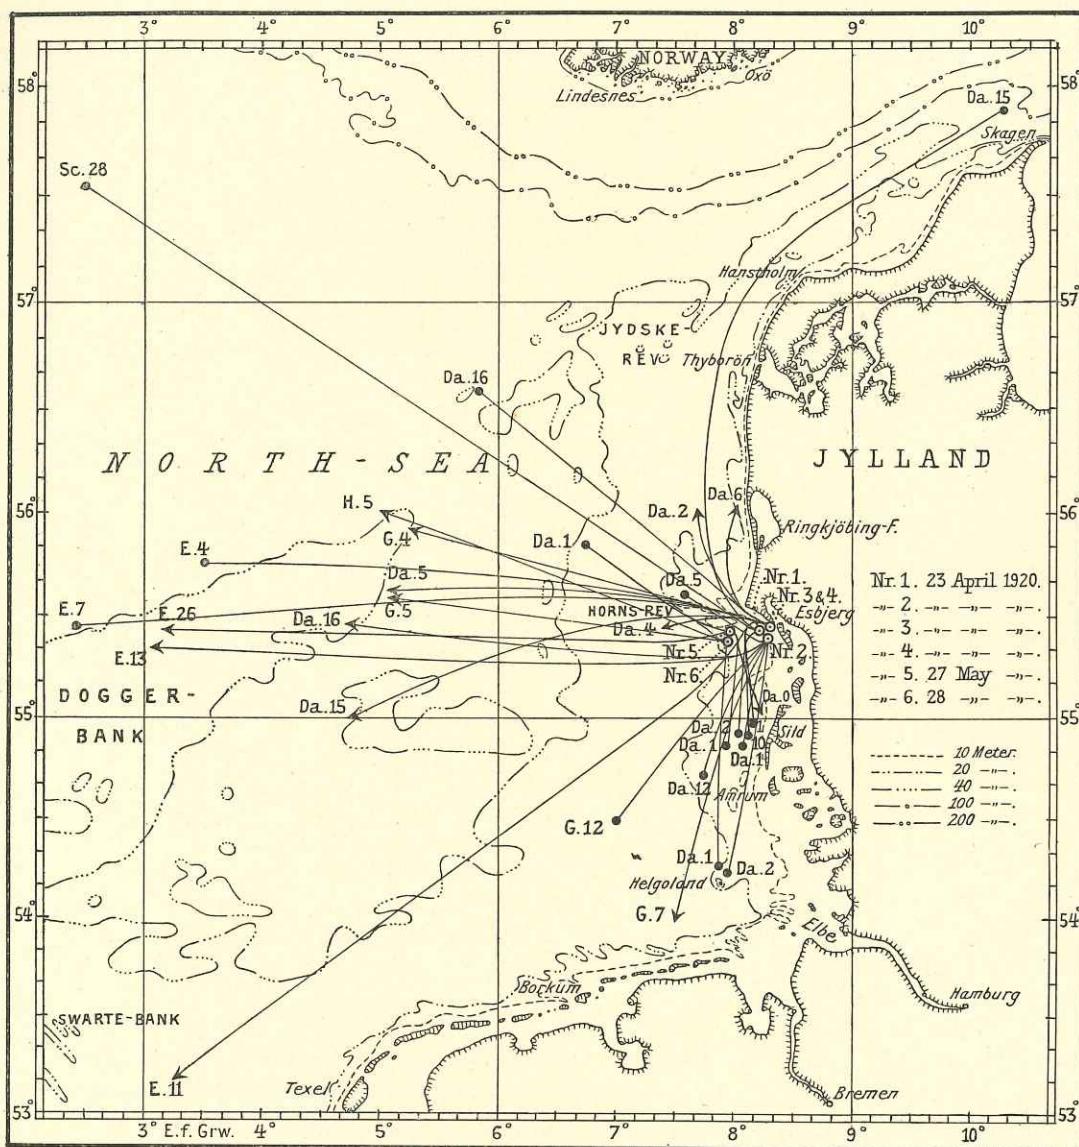

Fig. 10. *Marking experiments with plaice in the spring of 1920.*  
*Recaptures west of  $7^{\circ} 34' E.$  Long. or south of  $55^{\circ} 00' N.$  Lat. or north of  $56^{\circ} 00'.$*

known being only 16.4 m (16.0 for 22 recaptures in May and 16.6 for 42 recaptures in June). During July no plaice were recovered, but during August 7 specimens were secured (4 ♂♂ and 3 ♀♀), and of the 6 depths known, the average was 16.9 m. During the interval between August 1920 and 1st of Oct. 1923 only 6 more specimens were recovered, and of these, two males, one of 35 cm (growth: 3 cm) and another of 33 cm (growth: 6 cm), were caught during October 1920 at the north-east end of the Dogger Bank. In December a male of 31 cm (growth: 3 cm) was recovered in the area B<sub>4</sub> west of List. During the following spring a male of 32 cm (growth: 7 cm) was recaptured in A<sub>3</sub> west of List and a female of

27.5 cm (growth: 3 cm) west of Knude Deep. Finally a female of 38 cm (growth: 14 cm) was caught on the Dogger Bank in July 1922.

It appears from these two experiments that the seaward migration during the summer is much less pronounced from these grounds of depths 15—16 cm than from Graa-Deep.

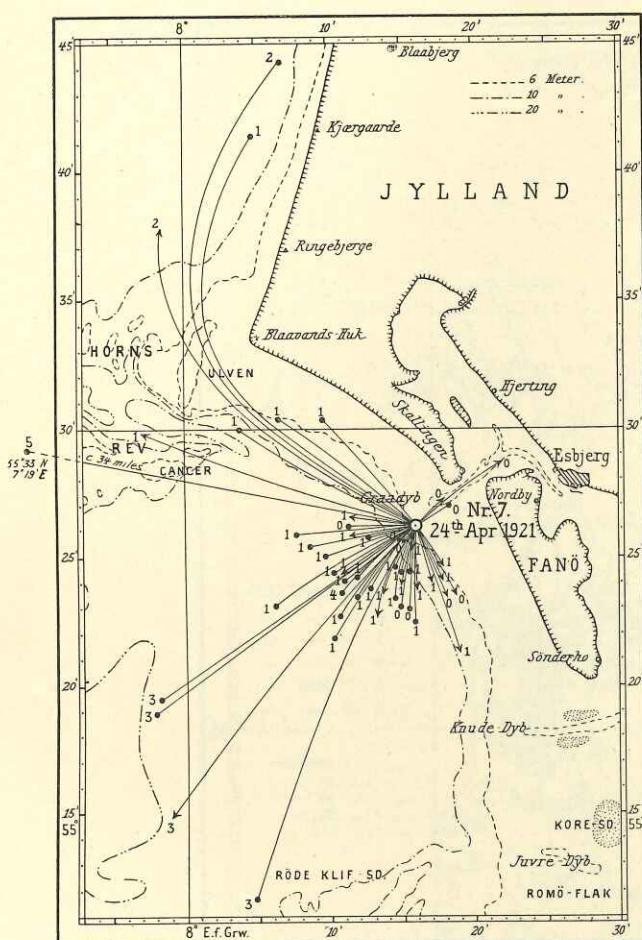

Fig. 11. Marking experiment with plaice on 24th of April 1921.  
Females denoted by a spot, males by an arrow head.

No. 8 had travelled towards N.W., and those of Exp. No. 9 towards N.N.W. But obviously these different directions only indicate that the grounds particularly worked by the fishermen during May were situated in the directions mentioned above from the three stations of liberation.

In Fig. 10 is given a survey of all the plaice in the experiments Nos. 1—6 which have been recovered west of  $7^{\circ} 34'$  E. Long., or south of  $55^{\circ}$  N. Lat., or north of  $56^{\circ}$  N. Lat. It will be seen that the plaice liberated south of Horns Reef have shown much more inclination to migrate westwards and southwards than northwards across the reef.

*Marking experiment No. 7* (Fig. 11). On 24th of April 1921 100 plaice were liberated at Graa Deep bar, at  $55^{\circ} 26'$  N. Lat.,  $8^{\circ} 16'$  E. Long. (Depth: about 4 m).

*Marking experiment No. 8* (Fig. 12). On 24th of April 1921 150 plaice were liberated off Fanø, at  $55^{\circ} 23'$  N. Lat.,  $8^{\circ} 17'$  E. Long. (Depth: 10 m).

*Marking experiment No. 9* (Fig. 13). On 24th of April 1921 100 plaice were liberated west of Sønderho, at  $55^{\circ} 20'$  N. Lat.,  $8^{\circ} 18'$  E. Long. (Depth: 10 m).

In these three experiments a total of 350 plaice (169 ♂♂ and 181 ♀♀) was liberated from three stations west of the island of Fanø. During April 50 specimens (23 ♂♂ and 27 ♀♀) were recovered at places of somewhat greater depths than where they were liberated, the average depths of the places of recapture being 11.5 m. Only one specimen of these, a male, was captured in B<sub>4</sub>, the rest being in A<sub>3</sub> south of Horns Reef. During May 110 specimens (51 ♂♂ and 59 ♀♀) were recaptured, 106 of them in A<sub>3</sub> south of Horns Reef on the average depth of 13 m (for 2 specimens the place of recapture is unknown). The recaptures took place particularly south-west of Graa-Deep so that the recovered plaice of experiment No. 7 had migrated chiefly towards S.W., whereas those belonging to Exp.

During June 6 specimens (2 ♂♂ and 4 ♀♀) were recaptured north of Horns Reef in A<sub>3</sub> and 2 females south of the reef in A<sub>3</sub>.

During July 8 specimens were recovered, one female in C<sub>2</sub>, one in B<sub>4</sub>, and 4 females and 2 males in A<sub>3</sub>, all in the western part of A<sub>3</sub> south of Horns Reef. Finally during August one female was caught in A<sub>3</sub> and during September one female in B<sub>4</sub>.

The experiments again indicate a distinct seaward migration during the summer.

#### b. Percentage of marked plaice recaptured.

Of the 850 plaice liberated in the spring experiments of 1920 and of 1921 46 % (Table 25) were recaptured, and 44 % within the first year after liberation. This is a smaller percentage of recaptures than that found from the spring experiment on the Horns Reef grounds in March or April during 1906—1912<sup>1</sup>, when the percentage of recaptures within a year was 53. It appears, however, from these experiments that the earlier in the spring the experiments are carried out, the greater is, on the whole, the percentage of recapture, and for the years of the period 1906—1912 in which the experiments took place after the 14th of April the percentage was only 46. The difference of season may therefore chiefly account for the different results in 1906—1912 and in 1920—1921.

In Table 25 we find some slight evidence that the percentage of recapture is greater for marketable plaice than for undersized plaice, further that among plaice of the same length-group the percentage of recapture is greater for females than for males, and that accordingly the percentage of recapture is, on the whole, greater for females than for males, the females liberated having a greater average length than the males (see Table 24).

In the experiments of 23rd of April 1920 (see Table 26) only 2 % were recaptured during the first month after liberation, and the chief part of the remainder have found time before capture to emigrate to the deeper grounds, where 26 % of the liberated

<sup>1</sup> A. C. JOHANSEN 1915, Table 4 p. 23.

plaice are caught during the second month after liberation together with the plaice liberated on these grounds on 27th and 28th of May. Of these plaice 32.5 % are captured during the first month after liberation and only 0.5 % during the second. In the experiments of April 1921, which took place not far away from the stations of the experiments of April 1920, 40 % of the liberated plaice were recaptured during the first month and only 8 % during the second. In all the three sets of experiments the number of recaptures occurring more than two months after the liberation, is small as compared with the number of those occurring during the first two months (see Table 27), and it is especially so in the experiments of April 1921.

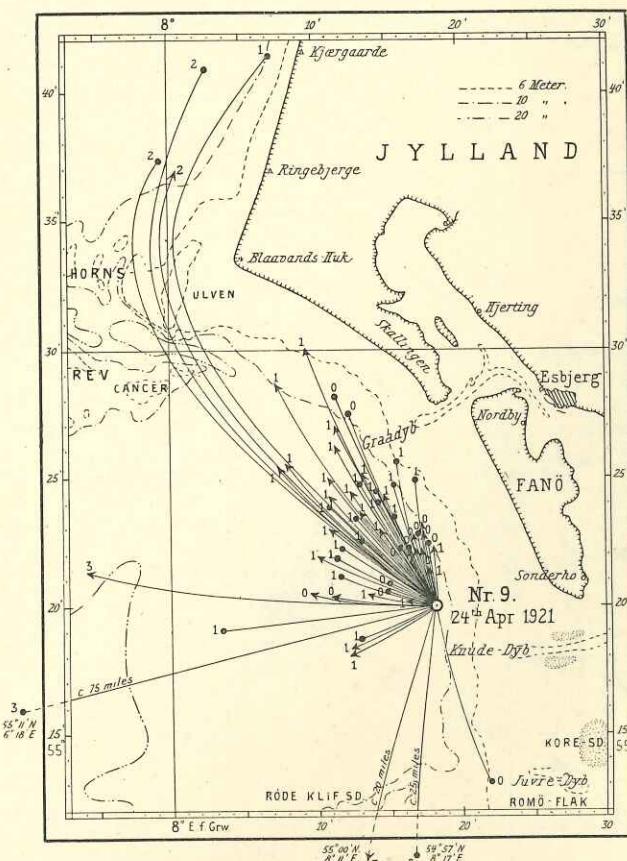

Fig. 13. Marking experiment with plaice on 24th of April 1921.  
Females denoted by a spot, males by an arrow head.

tween September 1920 and May 1921 incl. We have found the average increase of length in these 30 cases to be 6.1 with the standard deviation 0.6. As there must have been appreciable growth during Sept.—Oct. as well as during April—May and as this must tend to increase the standard deviation of the 30 observed values, we may probably assume that the standard deviation of the annual growth is not greater than 0.6.

27.—28. May 1920 .....	79	82	1	15	1
24. April 1921 .....	180	78	15	7	0

<sup>1</sup> A large percentage of the recaptured plaice were living when remeasured; when they were dead no correction for shrinkage was applied, as informations about the condition of the dead plaice are generally lacking.

The previous determinations of annual growth by means of marking experiments carried out on the Horns Reef grounds suffer from at least as great uncertainty, but the growth for the years 1908—1912 being only 5.3, 3.1, 4.6, 4.5, and 3.5 cm respectively, or on an average 4.2 cm, there can hardly be any doubt that the growth during these years was smaller than during 1920. During the years 1905—1907,

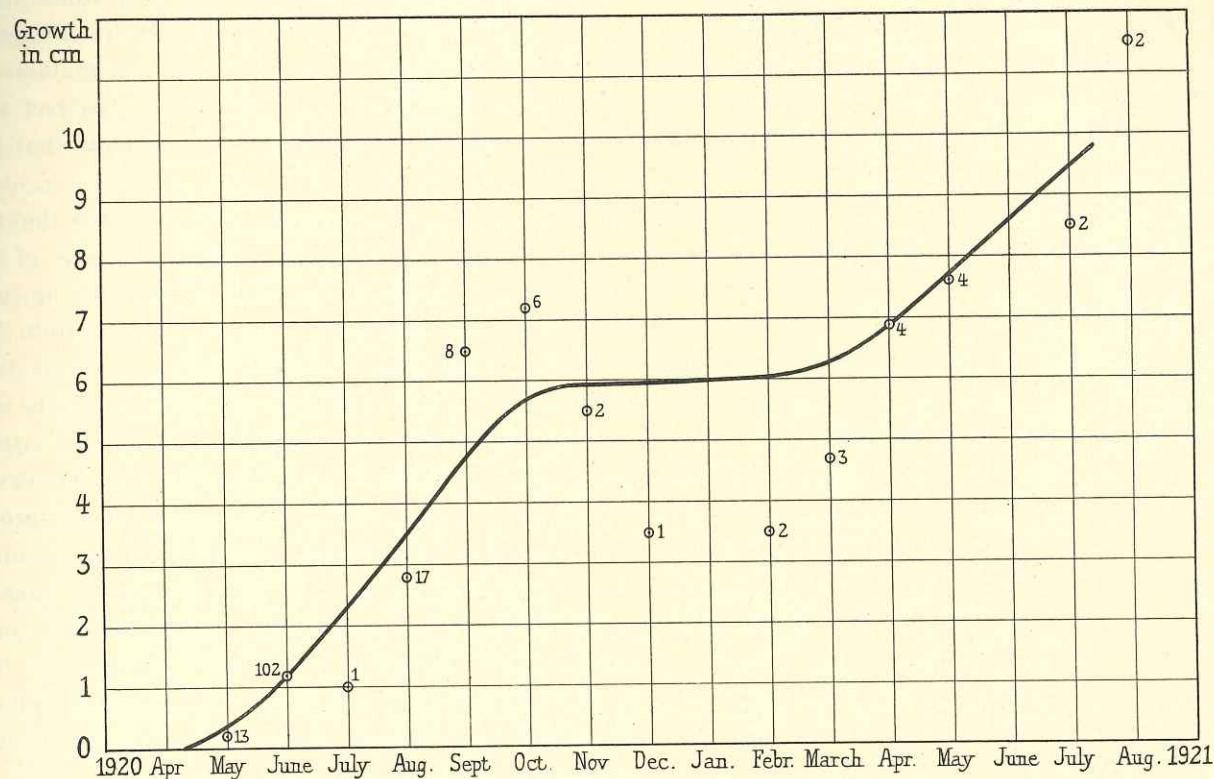

Fig. 14. Rate of growth of marked plaice liberated south of Horns Reef in the spring of 1921.  
The figures indicate the number of observations from which the means for each month have been calculated.

however, the annual growth was found to be 7.9, 6.1 and 7.7 respectively, which is approximately the same as during 1920.

In the experiments of 1921 all the recaptures occur before the end of the first period of growth, and 92 % of them during the first two months after liberation, so that they hardly give any valuable informations about growth. The 8 specimens recaptured during June have had an average growth of only 0.2 cm and the 8 specimens recaptured during July an average growth of 2.1 cm, which slightly indicates a smaller growth during 1921 than during 1920.

## VII. Summary.

On the basis of the fishing experiments with otter-trawl undertaken during the cruise of the "Dana" in September 1922 we have mapped out the density, the average length in age-groups, and the relative frequency of the two sexes in the Horns Reef area, and found the following characteristic features. The I- and II-groups occur with unusual frequency south of the Horns Reef inside the 30 metres curve especially in the region west of Graa Deep. At the same place the average length for each of these age-groups is considerably smaller than north and south of that place. The density for each age-group is, on the whole, distinctly smaller in the northern part of A<sub>3</sub> than in that lying south of Horns Reef. Outside the 20 metres curve the density of plaice older than three years is about the same north as south of Horns

Reef, but the average length for each age-group is considerably greater in the northern than in the southern area. Indeed, the growth is so different that when considering the density of marketable plaice we find that, outside the 20 metres curve the density is about five times as great north of Horns Reef ( $B_c$ ) as south of the Reef, ( $B_a$  and  $B_b$ ), although for each of the age-groups the maximum density is always found south of the reef. In the whole area investigated, except inside the 20 metres curve south of Horns Reef, the III-group is the dominant age-group among the marketable plaice, but along with this the IV-group forms quite a considerable proportion of the total, whilst the II-group is only of account as marketable plaice north of Horns Reef and in the southern area outside the 30 metres curve. South of the reef and inside the 30 metres curve, where the II-group is especially dense, the growth has been so slow that the size-limit has not yet been reached.

An investigation of the relative frequency of the two sexes in each age-group has shown that the females are relatively more frequent near the coast than further seawards and also that for each of the areas the relative frequency of females increases from one age-group to the next older. Considering in a bulk all plaice older than one year we notice a diminution in the relative frequency of females from the coast outwards. The sum for all the stations of individuals of an age-group caught per hour shows that a slight increase is found in the relative frequency of females with increasing age, but this may be explained by a surplus of the oldest males having probably migrated out of the area investigated, since they are in a predominant majority in the western part of this area. The distribution of males and females is explained by assuming that the males have a greater inclination than the females of the same age-group to leave the coastal grounds. The plaice dealt with here were all judged to be immature, and the peculiar numerical distribution of males and females can not be due solely to the mature males having already emigrated out of the investigated area, as the increasing relative frequency of males from the coast outwards has been already quite distinctly observed in the II-group, of which certainly no individual has attained maturity, and which hardly spread westward of the area investigated. For each station it is noticed that the average length of females is, as a rule, slightly greater than that of the males of the same age-group. Comparing the bulk of females and of males of an age-group from the investigated area south of Horns Reef or north of the reef, this difference disappears, and therefore we are inclined to think that at this age the growth is the same for males and for females, and that the difference in average length at a certain place, is simply brought about by the larger males having emigrated at a greater rate than females of the same length.

Fishing experiments as extensive as these undertaken in September 1922 have not previously been carried out in the Horns Reef area during the autumn, and consequently our comparison of the state in Sept. 1922 with that in former years gives less certain results than those stated above. The area best investigated is that west of Graa Deep inside the 30 metres curve, where the density of all the age-groups and especially of the I- and II-groups appears to be at least three times as great in September 1922 as in the autumn of the years 1903—1905. The investigations undertaken during the spring of 1907 also indicate a much smaller density, than in September 1922. The earlier observations taken north of Horns Reef are not very numerous; but they seem to indicate that, in 1922, the density is comparatively great outside the 20 metres curve and comparatively small inside that curve.

As regards the growth of the plaice the rather scarce measurements from 1905 indicate that the average lengths in the II—IV-groups were in 1905, in the area west of Graa Deep inside the 30 metres curve 4—6 cm greater than in 1922. The average lengths in the same age-groups were in  $C_2$  only a couple of centimetres greater than in 1922, so that we may suppose that it is the growth rate in the areas  $A_a$  and  $B_a$  which were densely populated in 1922, that has altered especially. A comparison with the investigations during the spring of 1907 show that the average length of the II-group north of Horns Reef, is in 1922 not as much below the previous value as that occurring south of Horns Reef, which confirms the supposition that the altered growth rate is connected with the considerable crowding of the I- and II-groups west of Graa Deep.

A comparison of the length for various age-groups, together with the information obtained from the marking experiments undertaken in 1920 leads us to conclude that the small average lengths observed in September 1922 are chiefly the results of an abnormally slow growth during 1922 and perhaps during 1921.

The data from the years 1903, 1905, and 1907 confirm, on the whole, the observation that the relative frequency of females decreases from the coastal waters seawards. They slightly indicate that the females are relatively less frequent on the Horns Reef grounds in 1922 than in 1903 and 1905, what may be connected with a later attainment of maturity and a consequently later segregation of males and females.

The samples of marketable plaice from the Horns Reef area during September to November 1922, illustrate by the distribution of the fishing-places of the catches, the results found from the fishing experiments concerning the density of marketable plaice. Of the 171 samples from the area investigated in September, 145 have originated from the part of  $B_4$  situated north of Horns Reef, where we have found the marketable plaice to be three to four times as dense as in any of the other areas investigated. The samples from  $B_4$  (which all arise from this northern part, named by us  $B_6$ ) as well as those from  $A_3$  show that the relative frequency of plaice over 30 cm has decreased very much since 1919, both as compared with the total number of marketable plaice and with plaice over 27 cm in length. The samples from that part of  $C_2$ , which lies south-east of the north-eastern end of the Dogger Bank also show a decreasing length from 1919 to 1922, when the average length of plaice is even smaller than in 1916. There can be no doubt that this is chiefly explained by the restriction on fishing during the War and the fishing being carried on again more intensely from and after 1919, which caused the average age of marketable plaice to be particularly high in 1919. As regards  $B_4$ , we find in the exceptionally slow growth during the summer of 1922 and perhaps of 1921, a cause that must also work towards a decline in the number of the plaice over 30 cm in length as compared with plaice between 27 and 30 cm.

The marketable samples from  $B_4$  and  $A_3$  measured in the autumn of 1922 are also inferior in length as compared with samples from the years 1904—1905, and this is probably due to the slower growth during the years 1921—1922.

### Tables of Measurements A.

The following tables give the results of fishing experiments carried out with a 50 feet otter-trawl with extra cod-end.

With one exception (St. 2820) the lengths of all the plaice caught during an experiment have been measured. At most of the stations all the plaice, except those of the 0-group, have been examined as to sex, and as to age by means of otoliths. At some of the stations the age and sex determination of the most numerous length-groups have only been undertaken for a portion of the specimens; their number are then given in a parenthesis, after the number calculated by distributing the total specimens of a length-group proportionately to the specimens examined. At such stations it has sometimes been possible to determine the age of the smallest specimens of the I-group alone by means of their lengths, if so the determination of sex has not been carried out, and the specimens of such length-groups have been distributed equally among males and females. When no figures in parenthesis occur in a table, all individuals excepts those of the 0-group have been age- and sex-examined.

All the specimens examined as to sex have been found immature; but it is hardly possible in all cases so early as in September to decide whether an individual will reach maturity in the approaching spawning-period or not.

### Table of Measurements B.

The following table records the measurements of lengths of marketable plaice landed in Esbjerg. The size-limit of plaice for sale in Denmark is 257 mm for the total length of the fish. For plaice landed in Esbjerg for export the size-limit is as follows:

From March 1st till Sept. 30th 240 mm  
,, Oct. 1st till Febr. 28th (29th) 225 mm

The measurements of the table are given in centimetres with omission of fractions of a centimetre, so that for instance the frequency stated for 27 cm indicates the number of individuals of length between 27 and 28 cm.

## Dansk Resumé.

*Kirstine Smith: Om Rødspættebestanden i Horns Rev Omraadet i Efteraaret 1922.*

### I. Indledning. Observationsmateriale.

Savnet af et Undersøgelsesskip har i nogle Aar stillet sig hindrende i Vejen for Fiskeriforsøg i den aabne Nordsø fra dansk Side. Det har kun været muligt at følge Rødspættebestandens skiftende Tæthed og Vækst gennem de Oplysninger, som Fiskeristatistiken og Undersøgelser af Markedsrødspætterne kunde give. Skønt man herved var i Stand til i store Træk at spore Virkningerne af Krigsaarenes indskrænkede Fiskeri, har Savnet af mere direkte Oplysninger været meget føleligt. Paa den ny Undersøgelsesdamper »Dana«s første Togt i de danske Farvande var det derfor en af Hovedopgaverne at udføre Fiskeforsøg med særligt Henblik paa Rødspætten.

Under Togtet i September 1922 foretog Dr. A. C. JOHANSEN 33 Fiskeforsøg paa Stationer i Horns Rev Omraadet (se Fig. 2). Redskabet var en 50 Fods Ottertravl med ekstra Omhyllingsnet om den bageste Ende af Travlen. Forsøgene varede fra en halv til to Timer, og alle Rødspætter i Fangsten blev talt og som Regel maalt. Ved de fleste Stationer blev Alderen bestemt ved Otolith og Kønnet undersøgt for alle Individer undtagen 0-Gruppens. Paa 12 Stationer, hvor Fangsterne var meget store, blev i de talrigst repræsenterede Længdegrupper Alder og Køn kun undersøgt for en Del af Individerne, og Resten blev fordelt proportionalt med de undersøgte. Observationerne meddeles i "Tables of Measurements A".

Ved Siden af disse Fiskeforsøg blev der i Efteraaret 1922 udført Maalinger af Markedsrødspætter landede i Esbjerg. Der blev maalt 23,299 Fisk fordelt paa 247 Prøver, hvoraf 145 stammede fra Fangster foretaget i den Del af det internationale Felt B<sub>4</sub>, som ligger nord for Horns Rev, og som i Efteraaret 1922 var meget rigere paa Markedsrødspætter end det endnu tættere befolkede Omraade vest for Graadyb. Maalingerne meddeles i "Table of Measurements B".

Endelig er her behandlet Resultaterne af Mærkningsforsøgene udført i Foraarene 1920 og 1921 syd for Horns Rev.

### II. Rødspættebestandens Sammensætning.

#### A. Rødspætternes Tæthed.

Af "Tables of Measurements A" er beregnet det Antal Rødspætter af hver Aldersgruppe, som fanges pr. Time med en 50 Fods Ottertravl, og Resultaterne er meddelt paa Kortene i Fig. 1. Da Tallene varierer stærkt selv mellem Stationer, som ligger nærværd hinanden, giver det et bedre Overblik at betragte Middel-værdier for Grupper af Stationer. Vi har derfor grupperet Stationerne efter seks Felter, der ligesom de internationale Areas til Dels begrænses af Dybdekurver.

Inddelingen, som er angivet paa Fig. 2, er følgende:

A <sub>a</sub>	syd for Horns Rev, Dybde:	0—20 m
A <sub>b</sub>	nord »	»      »      »      0—20 »
B <sub>a</sub>	syd »	»      »      »      20—30 »
B <sub>b</sub>	syd »	»      »      »      30—40 »
B <sub>c</sub>	nord »	»      »      »      20—40 »
C .....	»	over 40 »

Den gennemsnitlige Fangst pr. Time for hver af disse Felter er givet i Table 1, og for Aldersgrupperne 0—IV fremstillet grafisk i Fig. 4.

a. Tæthedens Variation i September 1922.

Kortene i Fig. 1 illustrerer tydelig det velkendte Forhold, at de unge Rødspætter lever i Nærheden af Kysten og efterhaanden, som de bliver ældre, gaar ud paa større Dybder og spredes over større Omraader, idet nogle af de ældre Individer stadig bliver tilbage i Kystomraadet.

0-Gruppen findes i September især i A<sub>a</sub> og A<sub>b</sub> og er ikke fanget paa dybere Vand end 23 m. Den findes gennemgaaende ikke synderlig hyppigere i A<sub>a</sub> end i A<sub>b</sub>. Alle de andre Aldersgrupper er omtrent lige talrigt repræsenterede i B<sub>a</sub> og i A<sub>a</sub> og er i disse Felter adskillige Gange saa talrige som i A<sub>b</sub>. Indenfor 20 Meterkurven er den samlede Tæthed af Rødspættebestanden, som den fremgaar af disse Fangster, saaledes tre Gange saa stor syd for Horns Rev som nord for Revet. I- og II-Gruppen hører især hjemme i A<sub>a</sub> og B<sub>a</sub>, og de har begge, betragtet i Retningen Nord til Syd, en maksimal Tæthed omtrent vest for Graadyb. I-Gruppen forekommer ikke paa større Dybder end 36 m. II-Gruppen findes ved alle Stationer undtagen to af de vestligste. III-, IV- og V-Gruppen er især hyppig forekommende i A<sub>a</sub>, B<sub>a</sub>, B<sub>b</sub> og B<sub>c</sub>. Udenfor 20 Meterkurven er Individer af disse Aldersgrupper ikke væsentlig talrigere syd for end nord for Horns Rev, og i Retningen Nord til Syd finder man ikke for disse Aldersgrupper noget Maksimum af Tæthed vest for Graadyb.

Vi har her sammenlignet Tæthedens for samme Aldersgruppe i forskellige Dele af Undersøgelsesomraadet; dersom vi i Stedet for efter Alder grupperer Rødspætterne efter Størrelse og f. Eks. undersøger den vekslede Tæthed af Markedsrødspætter, kommer vi til ganske andre Resultater paa Grund af den forskellige Væksthastighed nord og syd for Horns Rev. Markedsrødspætternes Tæthed er behandlet under D.

b. Sammenligning af Tæthedens i 1922 med Tæthedens i Aarene 1903—1907.

Fra dansk Side har der ikke siden Foraaret 1907 været foretaget Fiskeforsøg med Ottertravl, og Otolithundersøgelser blev først almindelig gennemført fra Sommeren 1905. Fra Fiskeforsøgene foretaget i 1903—1904 og i Foraaret 1905 har vi derfor ikke noget Maal for Tæthedens af de enkelte Aldersgrupper, men vi kan for Rødspætter af samme Størrelsесgruppe sammenligne Tæthedens med den i 1922 forefundne.

I Fig. 2 og Fig. 3 meddeles Tæthedens af Rødspætter af Længden 10—19 cm. Det fremgaar af disse Kort, at Tæthedens af saadanne Rødspætter i A<sub>a</sub> og B<sub>a</sub> i Efteraarene 1903 og 1904 og i Foraarene 1904 og 1905 var ca. 3 Gange saa stor som i Efteraaret 1922. I A<sub>b</sub> synes Tæthedens i September 1922 mindre end i Efteraarene 1903 og 1904, men større end i Foraarene 1904 og 1905.

Som det vil ses i det næste Afsnit, har Rødspætternes Vækst i Horns Rev Omraadet i 1922 været usædvanlig ringe, saa at Størrelsесgruppen 10—19 cm ikke havde samme Alderssammensætning i 1922 som i Efteraarene 1903—1905. Ifølge Undersøgelser paa to Stationer i den nordlige Del af A<sub>a</sub> og B<sub>a</sub> omfatte Størrelsесgruppen 10—19 cm i September 1905 I-Gruppen og omtrent to Trediedele af II-Gruppen, medens den i September 1922 i den nordlige Del af A<sub>a</sub> og B<sub>a</sub> bestod af I-Gruppen og hele II-Gruppen. Da Væksten i 1903 og 1904 ifølge Mærkningsforsøgene var langsommere end i 1905, maa man antage, at mindst to Trediedele af II-Gruppen i de Aar var mindre end 20 cm, og paa den anden Side synes I-Gruppens Vækst, at skifte saa lidt fra Aar til Aar, at man kan antage, at den ogsaa i Efteraarene 1903 og 1904 praktisk talt udelukkende bestod af Individer over 9 cm. Regner man med, at I-Gruppen og II-Gruppen i begge Perioder var lige hyppige i Fangsterne, skulde herefter de ændrede Vækstforhold — under Forudsætning af, at Tæthedens for begge Aargange havde holdt sig uforandret — have bevirket, at Tæthedens af Individer i Størrelsесklassen 10—19 cm var blevet forøget i Forholdet

$$\frac{1+1}{1+\frac{2}{3}} = \frac{6}{5}$$

fra Perioden 1903—1904 til 1922. I Stedet for en saadan Forøgelse af Tæthedens har vi i de nordlige Dele af A<sub>a</sub> og B<sub>a</sub> fundet en tre Gange saa stor Tæthed, hvoraf vi maa slutte, at baade I- og II-Gruppen har været meget talrigere repræsenterede i 1922 end i 1903—1904.

Fra Fiskeforsøgene i September 1905 har man fundet de i Table 2 anførte Tæthedener. En Sammenligning med Table 1 viser, at paa Stationerne i A<sub>a</sub> og B<sub>a</sub> er den samlede Tæthed omrent tre Gange saa stor i 1922 som i 1905, og at Tætheden for II-Gruppen maaske er tiltaget endnu stærkere. Men paa den eneste Station fra A<sub>b</sub>, som er undersøgt i 1905 er saavel Tætheden af Størrelsesgruppen 10—19 cm som den totale Tæthed større end de tilsvarende gennemsnitlige Værdier for A<sub>b</sub> i 1922.

I Foraaret 1907 fandt man, som det vil ses af Table 3 og Fig. 3, en endnu ringere Fangst pr. Time end i Efteraaret 1905. For I-Gruppen og maaske for II-Gruppens Vedkommende er det rimeligvis delvis begrundet ved Fiskenes ringe Størrelse i Majmaaned. I hvert Fald er der ikke for III- og IV-Gruppens Vedkommende en saa enorm Forskel mellem Værdierne for 1907 og for 1922. Tæthederne for disse Grupper er i A<sub>a</sub> og A<sub>b</sub> omrent lige saa store i Maj 1907 som i September 1922, men i B<sub>a</sub> og B<sub>c</sub> meget mindre i 1907 end i 1922. Man vilde imidlertid paa Forhaand vente sig i Maj at finde en Ophobning af Individer af disse Aldersgrupper i A<sub>a</sub> og B<sub>a</sub>, som vil sprede sig i Løbet af Sommeren, naar Rødspætten vandrer ud paa dybere Grunde. Maaske er det derfor mere formaalstjenligt at betragte den gennemsnitlige Tæthed for alle Felter, og denne er for III- og IV-Gruppen omrent fire Gange saa stor i September 1922 som i Maj 1907.

De almindelige Indtryk man faar ved Sammenligningen mellem Resultaterne af Fiskeforsøgene i Perioden 1903—1907 med Resultaterne fra September 1922 er følgende:

Individer af hver af Aldersgrupperne I og II er i 1922 i det mindste tre Gange saa talrige vest for Graadyb indenfor 30 Meterkurven som i den tidlige Periode, og det samme er Tilfældet for III-, IV- og V-Grupperne, saavidt Oplysninger haves; men der er intet Vidnesbyrd om, at Tætheden udenfor 30 Meterkurven i 1922 har været større end i den tidlige Periode, og i Kystfarvandet nord for Horns Rev synes Tætheden i Efteraarene 1903—1905 at være i det mindste lige saa stor som i 1922.

Det sikreste og bedst begrundede af disse Resultater er den store Tilvækst af Individer af I- og II-Gruppen i Omraaderne A<sub>a</sub> og B<sub>a</sub>. Disse Aldersgruppens maksimale Tætheder falder i 1922 i A<sub>a</sub> og B<sub>a</sub>. Undersøgelsen fra 1903—1905 er ikke saa omfattende, at vi kan være sikre paa, at det ogsaa i disse Aar forholder sig saaledes; men paa den anden Side giver de i A<sub>a</sub>, B<sub>a</sub> og C undersøgte Stationer heller ingen Antydninger af det modsatte. Tæthedsundersøgelserne leder derfor til den Antagelse, at ogsaa Tætheden af de totale I- og II-Grupper syd for Horns Rev i 1922 var mindst to til tre Gange saa stor som i Perioden 1903—1905.

En Sammenligning mellem Table 4 og Fig. 1 viser, at Individer af 0-Gruppen i A<sub>a</sub> er adskillige Gange saa talrige i 1922 som i 1903—1905. Ved Fiskeforsøgene med Yngeltravl ved Jyllands Vestkyst har man ikke fundet, at 0-Gruppens Tæthed i 1920 og 1921 var usædvanlig stor i Sammenligning med Tætheden i Aarene forud for Krigen. Men disse Forsøg er ikke saa omfattende, at vi derfor tør udelukke den Mulighed, at Rødspætteynglen i Nordsøen i det store og hele har været rigere i 1920 og 1921 end sædvanlig.

Den store Rigdom paa Individer af I- og II-Gruppen syd for Horns Rev i September 1922 begunstiger den Antagelse, at Rødspætteynglen i 1920 og 1921 har været usædvanlig talrig, og de Forandringer, som ellers er iagttaget i Nordsøens Rødspættebestand, støtter denne Formodning. Markedsrødspætternes<sup>1</sup> Antal naaede sandsynligvis et Maksimum i 1919 som Følge af Krigstidens Fredning. Da Markedsrødspætternes Gennemsnitsalder af samme Grund var vokset under Krigen viste de ynglende Rødspætters Antal rimeligvis et forholdsvis endnu mere udpræget Maksimum, og det er sandsynligt, at deres Antal endnu i 1920 og 1921 var betydelig større end i det sidste Decennium forud for Krigen.

#### B. Alder og Længde.

##### a. Gennemsnitslængder for de forskellige Aldersgrupper i September 1922.

De i "Tables of Measurements A" meddelte Gennemsnitslængder for Aldersgrupper er fremstillede paa Kortene i Fig. 5. Disse viser, at Gennemsnitslængden for hver Aldersgruppe vokser i Retning fra Kysten

<sup>1</sup> Ved Markedsrødspætter forstaas her Rødspætter over 25 cm Totallængde.

udefter. Rødspætterne er ikke alene naturligt sorterede efter Alder, men ogsaa de enkelte Aldersgrupper er delvis sorterede efter Længde. Dette iagttaages allerede klart for 0-Gruppen og endnu tydeligere for de følgende Aldersgrupper. Men ved Siden af denne Gradation i Retning fra Kysten udad, bemærkes der karakteristiske Forskelle mellem Gennemsnitslængden syd og nord for Horns Rev.

Gennemsnitslængden af 0-Gruppen (se Table 5) er allerede noget større nord for Horns Rev i  $A_b$  end syd for Horns Rev i  $A_a$ . For de følgende Aldersgrupper er der en endnu større Forskel mellem Gennemsnitslængderne i  $A_b$  og  $A_a$ , saa at II-, III- og IV-Gruppen i  $A_b$  har omtrent de samme Gennemsnitslængder som henholdsvis III-, IV- og V-Gruppen i  $A_a$ . Gennemsnitslængden er imidlertid ikke meget større i  $B_a$  end i  $A_a$ , især ikke for I- og II-Gruppen. Dette saavelsom Tæthedsfordelingen tyder paa, at der er en livlig Udveksling af Rødspætter mellem  $A_a$  og  $B_a$ , og at Horns Rev danner en Grænse mellem  $A_a$  og  $A_b$ , saa at hvert af disse Omraader har en særpræget Bestand. For baade I- og II-Gruppen bemærker man i Retningen Nord—Syd et Minimum for Gennemsnitslængden i  $A_a$  og  $B_a$  vest for Graadyb paa samme Sted, hvor disse Aldersgrupper viste et Maksimum af Tæthed. For III- og IV-Gruppen findes ikke et saadant tydeligt Minimum, men Gennemsnitslængden aftager i det store og hele i Retning fra Nord til Syd.

Forskellen mellem Længden af Rødspætter af samme Alder nord og syd for Horns Rev illustreres yderligere i Table 6. Denne giver for hver Aldersgruppe Længdefordelingen pr. 100 Individer og den gennemsnitlige Længde i de to Omraader ( $A_a + B_a + B_b + C$ ) og ( $A_b + B_c$ ). Under Forudsætning af, at Gennemsnitslængderne for hver Aldersgruppe er de samme i 1921 som i 1922, finder man af Table 6 den i Table 7 angivne aarlige Vækst. Denne Tabel viser, at Væksten i det andet og i det tredje Leveaar er omtrent 2 cm større nord for Horns Rev end syd for Revet. Det synes rimeligt, at dette skyldes en bedre Ernæring i det nordlige Omraade end i det sydlige, hvor vi specielt for I- og II-Gruppen fandt, at Tæthed var overordentlig stor. Tæthedens af disse Aldersgrupper i  $A_a$  og  $B_a$  er 6—7 Gange saa stor som i  $A_b$  og 9—10 Gange saa stor som den samlede Tæthed af ældre Rødspætter i  $A_a$  og  $B_a$ , hvorfaf følger, at disse Aldersgruppens Tæthed har en væsentlig Indflydelse paa Mængden af Næringsstof pr. Individ. Paa samme Sted som I- og II-Gruppens maksimale Tæthed fandt vi for konstant Afstand fra Kysten en minimal Gennemsnitslængde for baade I- og II-Gruppen, men ikke for III- og IV-Gruppen. Dette sidste er ikke forbavsende, da disse Aargange allerede har spredt sig over et større Omraade og maa antages at have foretaget saa vide Vandringer, at deres Ernæringstilstand i meget ringere Grad er bestemt ved Betingelserne paa det Sted, hvor de fanges, skønt der ogsaa for disse Aargange er en tydelig Gradation i Længden fra Kysten udad og fra Syd til Nord. I Overensstemmelse med denne Betragtning viser Table 7 for det 4de og 5te Leveaar ingen væsentlig Vækstforskelse mellem det sydlige og det nordlige Omraade; udenfor 20 Meterkurven er der antagelig en friere Udveksling af Individer mellem de to Omraader end i  $A_a$ , og i  $B_b$  (udenfor 30 Meterkurven i det sydlige Omraade) er Tæthedens ikke større og muligvis Ernæringstilstanden ikke ringere end nordpaa i  $B_c$ .

#### b. Sammenligning mellem Gennemsnitslængderne for Aldersgrupper i 1922 og i 1905—1907.

De eneste, usorterede, otolithundersøgte Prøver fra tidligere Aar er de, i det foregaaende omtalte, fra September 1905 og April—Maj 1907. I Table 8 er Stationerne fra September 1905 sammenlignet med de nærmestliggende Stationer fra September 1922. Det ses, at der ingen væsentlig Forskel er mellem I-Gruppernes Gennemsnitslængde, men II-, III- og IV-Gruppernes Gennemsnitslængde er, som Table 8a viser, i  $A_a$  og  $B_a$  4—7 cm længere i 1905 end i 1922. En Betragtning af Kortene i Fig. 5 viser, at saa store Gennemsnitslængder for IV-Gruppen, som de i 1905 observerede, overhovedet ikke forekommer i 1922, og at de store Gennemsnitsværdier for II- og III-Gruppen, som i 1905 observeredes i  $A_a$  og  $B_a$ , i September 1922 først forekommer i de yderste Dele af  $B_b$ . Det er saaledes klart, at selv om de yngre Aldersgrupper skulde være stærkere koncentreret til Nærheden af Kysten i 1922 end i 1905, hvad man kunde tænke sig hændte samtidig med, at Gennemsnitslængden paa hvert Sted var aftaget, vilde dette ikke berøre Sammenligningen

synderlig. Vi skal derfor i det følgende betragte de Forskelle, som er anført i Table 8a, som en Tilnær melse til Forskellen mellem Gennemsnitslængden mellem de totale Aldersgrupper syd for Horns Rev.

Tidligere Undersøgelser i Horns Rev Omraadet har vist, at Væksten i de to første Leveaar ikke veksler meget fra Aar til Aar; af den Omstændighed, at Middellængden for I-Gruppen er den samme i 1905 og 1922, kan man derfor ikke slutte, at Væksten for de andre Aarsgrupper har været lige stærk i 1905 og 1922. Man maa tværtimod antage, at den betydelige Forskel mellem II-Gruppens Gennemsnitslængde i de to Perioder kan betragtes som et Maal for Vækstforskellen i  $(A_a + B_a)$  i de to Somre, skønt den endnu større Forskel for III- og IV-Gruppen lader formode, at Væksten i Sommeren 1904 ogsaa har været stærkere end i 1921. Da Gennemsnitslængderne fra Stationerne i C er meget mindre afvigende, tør man maaske antage, at Væksten derude har været omrent den samme i 1904—1905 og i 1920—1921, og at det er under Opholdet i Kystomraadet, at de i C fangede Rødspætter har været underkastede forskellige Livsbetingelser, som har bevirket en noget forskellig Vækst.

I Table 9 er Stationerne i  $A_a$  og  $A_b$  fra Foraaret 1907 sammenlignet med de nærmestliggende Stationer fra September 1922, paa den Maade, at en Aldersgruppe fra Foraaret 1907 sammenstilles med den nærmest yngre Aldersgruppe fra Efteraaret 1922. Forskellen mellem Gennemsnitslængderne fremgaar af Table 9a; da Væksten fra September til Maj det følgende Aar i 1906—1907 ifølge Mærkningsforsøgene maa anslaas til ca. 2 cm, bliver der, ogsaa naar man trækker dette Beløb fra, en betydelig Forskel tilbage for de tre ældste Aldersgrupper, som dog maaske ikke alene skyldes forskellig Vækst. Om Foraaret er der nemlig utvivlsomt i  $A_a$  og  $A_b$  en Ophobning af større Rødspætter, hvoraf i det mindste en Del i Slutningen af den foregaaende Sommer har levet paa dybere Vand, hvoraf følger, at de paa den Tid var større end Rødspætter af deres Aarsgruppe, som levede i  $A_a$  og  $A_b$ . Det har maaske derfor større Interesse at sammenligne Middelværdierne fra  $A_a$  og  $A_b$  for Foraaret 1907 med Middelværdierne for de totale Aldersgrupper fra Table 6. Herved findes de i Table 9b angivne Differenser, som viser, at naar man regner med en Vækst af 2 cm fra September 1906 til Maj 1907, bliver der endnu en betydelig Vækstforskeld tilbage mellem Aarene 1906 og 1922.

Med Benyttelse af de Oplysninger, som Mærkningsforsøgene fra 1905 og 1906 giver om Væksten, og de Oplysninger, som Tables 8a og 9b giver om Længdeforskellene for Aldersgrupper, ledes vi til det Skøn, at Væksten i Horns Rev Omraadet i 1922 for unge Rødspætter over to Aar gamle kun har været lidt over 3 cm. Om Væksten i 1921 maa vi antage, at den har været en Del ringere end i Aarene 1904 og 1905, da den ifølge Mærkningsforsøgene var henholdsvis 5.5 og 8 cm. For 1920 er Væksten ved Hjælp af Mærkningsforsøg (se Fig. 14) bestemt til ca. 7 cm. Det er derfor sandsynligt, at de usædvanlig smaa Gennemsnitslængder, som i September 1922 er observeret i Horns Rev Omraadet, alene skyldes en usædvanlig langsom Vækst i Somrene 1921 og 1922.

En lignende Aftagen i Vækst er fra engelsk Side iagttaget paa Linien Leman-Haaks for 1920 og de foregaaende Aar ved at sammenligne Gennemsnitslængder for Aldersgrupper iagttaget i 1920 og i 1905—1906.

#### C. Køn.

##### a. Talmæssig Fordeling af de to Køn i September 1922.

Table 10 giver for Aldersgrupperne I til IV Procenttallet af Hunner i hvert Felt. Beregningen er foretaget paa Grundlag at "Tables of Measurements A" ved at addere Antallet af Individer fanget pr. Time ved hver af Stationerne og bestemme Procenttallet af Hunner i Summen. Beregningen af Middelfejlene i Table 10 er baseret paa den teoretiske Middelfejl for en Bestemmelse af Kønnet i et enkelt Individ, og ved den videre Beregning er det nøje taget i Betragtning, om Kønnet virkelig er blevet undersøgt i hvert Individ, eller om Kønsbestemmelsen er et Resultat af Beregning.

Ser vi paa det sydlige Omraade omfattende  $A_a$ ,  $B_a$ ,  $B_b$  og C, viser Tabellen, at der er en tydelig Aftagen i Procenttallet af Hunner fra  $A_a$  gennem  $B_a$  og  $B_b$  til C. For Aarsgrupperne II til IV er der en

stadig Aftagen i Procenttallet fra Kysten udefter; for I-Gruppen er Procenttallet større i  $B_a$  end i  $A_a$ , men Forskellen er kun  $4.2 \pm 4.4$ . I det nordlige Omraade bestaaende af  $A_b$  og  $B_c$ , som er mindre tæt befolket, og hvorfra vi derfor har færre Observationer, kan man kun for I-Gruppen fastslaa en afgjort Aftagen af Procenttallet af Hunner fra  $A_b$  til  $B_c$ , men kun for III-Gruppen gaar Forskellen i modsat Retning, og den beløber sig kun til en Trediedel af dens Middelfejl. Der er derfor ingen Tvivl om, at for hver af Aldersgrupperne I—IV aftager den relative Hyppighed af Hunner i det store og hele fra Kystomraadet udad. I mange Tilfælde er Middelfejlen af Procenttallet af Hunner ved de enkelte Stationer saa store, at denne relative Aftagen i Hunnernes Antal tilsløres, men Kortet Fig. 6 over Procenttallet af Hunner i II-Gruppen illustrerer dog Forholdet ganske godt.

En relativ Aftagen i Antallet af Hunner fra  $A_3$  til  $B_4$  er paavist ved de engelske Undersøgelser i 1906, men ved disse fandt man igen en Tiltagen i den relative Hyppighed af Hunner fra  $B_4$  til  $C_2$ . Vore Undersøgelser i September 1922 omfatter imidlertid en saa ringe Del af  $C_2$ , at de ikke engang vilde kunne oplyse, om der øst for Dogger Banke var en Tiltagen.

Naar man i Table 10 sammenligner Procentallene for de forskellige Aldersgrupper i eet og samme Felt, bemærker man en Tiltagen af den relative Hyppighed af Hunner med voksende Alder. Kun tre Værdier i Tabellen ( $A_a$ , IV;  $A_b$ , III og  $B_a$ , I) bryder denne Regel, og de afviger højst fra deres Naboværdier med 0.6 Gange Middelfejlen paa Afgelsen. Ogsaa naar man betragter hele Omraadet under eet, er den relative Hyppighed af Hunner lidt større i III- og IV-Grupperne end i I- og II-Grupperne, men kun for I- og III-Gruppen nærmer Forskellen sig til to Gange dens Middelfejl. Da Stationerne ligger nærmest i  $A_a$  og  $B_a$ , hvor Hannerne af III- og IV-Grupperne er hyppigere end længere vestpaa, og da det maa antages, at et Overskud af Hanner af III- og IV-Grupperne er vandret ud af Undersøgelsesomraadet vestpaa, er det dog ikke raadeligt at betragte Tallene i Table 10 som et Vidnesbyrd om, at Hannerne af de samlede Aldersgrupper er tiltagende i relativ Hyppighed med tiltagende Alder.

Den simpleste Forklaring paa den fundne talmæssige Fordeling af Hanner og Hunner synes at være den, at Hannerne af enhver Aldersgruppe vandrer længere ud fra Kysten end Hunnerne. Dette forklarer for det første, at der i hver Aldersgruppe er et aftagende Procenttal Hunner, naar man bevæger sig fra Kysten ud paa dybere Vand, og for det andet, at paa ethvert Sted er Procenttallet af Hunner af den ældste Aldersgruppe større end for den næstældste og stadig videre aftagende med aftagende Alder. At Hannerne skulde vandre længere ud end Hunnerne er at vente i de Aldersgrupper, som indeholder modne Individer. Men alle de her undersøgte Rødspætter syntes umodne, og selv om det kunde tænkes, at Gradationen i Procenttallet af Hunner for III- og IV-Gruppens Vedkommende var opstaet alene ved, at en Del modne Hanner var udvandret vestpaa helt ud af Undersøgelsesomraadet, vilde denne Forklaring ikke kunne anvendes for II-Gruppen, hvoraf utvivlsomt intet Individ har naaet Modenheden, og som næppe forekommer paa dybere Vand end det her undersøgte. Vi maa altsaa antage, at, selv inden Modenheden er naaet, har Hanner af de unge Aldersgrupper en større Tilbøjelighed til at forlade Kystomraadet end Hunner af samme Alder.

Man ser af Kortene for II- og III-Gruppen i Fig. 5, at paa samme Station er Gennemsnitslængden i Reglen noget større for Hunner end for Hanner af samme Alder. Det samme Indtryk faar man ogsaa af Table 5, naar man sammenligner Gennemsnitslængderne af Hanner og Hunner for samme Felt. Det er imidlertid tvivlsomt, om dette hos disse unge Aldersgrupper skal opfattes som et Vidnesbyrd om hurtigere Vækst hos Hunner end hos Hanner. Naar de største Individer af en Aldersgruppe vandrer først ud, og naar Hannerne vandrer tidligere ud end Hunnerne, maa Resultatet — under Forudsætning af lige Vækst for de to Køn — blive, at paa hvert givet Sted er Gennemsnitslængden større for Hunner end for Hanner. Sammenligner man for hvert af de to Omraader ( $A_a + B_a + B_b + C$ ) og ( $A_b + B_c$ ) Gennemsnitslængderne for Hanner og for Hunner af samme Aldersgrupper, finder man da heller ikke, at Hunnerne er Hannerne overlegne i Størrelse. (Se Table 11.)

b. Talmæssig Fordeling af de to Køn iagttaget ved de danske Undersøgelser  
i Aarene 1903, 1905 og 1907.

Det synes at fremgaa af Tables 12 og 13, som giver Resultaterne af de danske Undersøgelser fra 1903, 1905 og 1907, at Hunnernes relative Hyppighed i Horns Rev Omraadet er større i September end om Foraaret. Paa begge Aarstider iagttager man ligesom i September 1922 en større relativ Hyppighed af Hunner i  $A_a$  end i  $B_a$ .

c. Har de to Køns relative Hyppighed ændret sig?

En Sammenligning af Table 10 med Tables 12 og 13 viser, at den relative Hyppighed af Hunner er væsentlig mindre i September 1922 end i September 1903 og 1905. Medens Hunnerne blandt Rødspætter over et Aar i September 1903 og 1905 var i afgjort Flertal, er de i September 1922 kun i nogenlunde sikkert Flertal i  $A_a$  og i afgjort Mindretal i  $B_c$  og C. De betragtede Rødspætter tilhører væsentlig Aldersgrupperne I—IV.

Tyske Undersøgelser af Markedsrødspætter fra den sydøstlige Nordsø tyder ogsaa paa, at Hunnernes relative Hyppighed er aftaget efter Krigen. Forskellen fra 1909 til 1919 er, som det ses af Table 14, meget paafaldende. Nedgangen er især fremtrædende for Aarets første Halvdel, da Fangsterne indeholder relativt mange store Rødspætter (over 40 cm lange), hvoraf man tør slutte, at det ikke mindst er i de ældre Aldersgrupper, at Hyppighedsforskydningen er sket.

Ogsaa de engelske Undersøgelser fra 1920 og 1921 i den sydlige Nordsø bringer Vidnesbyrd om en formindsket relativ Hyppighed af Hunner, særlig blandt V-Gruppen og ældre Aldersgrupper.

Vi har saaledes fra tre Grupper af Undersøgelser fundet Vidnesbyrd om et forøget Procenttal af Hanner efter Krigen. For Horns Rev Omraadet synes Forskellen i September 1922 allerede at spores i II-Gruppen, men i det engelske og det tyske Materiale synes Forskellen mest paafaldende for de ældre Aarsgrupper.

Man kan vanskelig tænke sig en enkelt Forklaring, som kan finde Anvendelse baade for de unge Aargange i Horns Rev Omraadet og for de ældre over fem Aar gamle. Før Krigen var der aabenbart i Nordsøens samlede Rødspættebestand en tydelig procentisk Aftagen af Hanner fra den Alder, ved hvilken Flertallet af Hanner blev modne, til ældre Aldersgrupper; men om denne større Dødelighed af Hanner skyldtes Fiskeriet eller »naturlige« Aarsager, er ikke opklaret. Man har tænkt sig den mulighed, at det skyldtes det Forhold, at de modne Hanner paa Ynglepladserne, hvor de opholder sig holdt sig saaledes, maatte Fiskeriets Indskrænkning under Krigen, især da det ikke mindst blev hæmmet paa Ynglepladserne, virke til at udligne Hyppighedsforskellen mellem modne Hanner og Hunner. Men herved forklares ikke, hvorfor Hannerne allerede inden Femaarsalderen skulde være relativt hyppigere. Hvis det forholder sig saaledes, kan den relative Aftagen af Hunner i Horns Rev Omraadet fra September 1903 og 1905 til September 1922 naturligt forklares ved en forskellig stedlig Fordeling af Hanner og Hunner i de to Perioder, og der er ingen Grund til at antage, at den relative Hyppighed af de to Køn har ændret sig for de totale Aarsgrupper.

<sup>1</sup> Skønt man ikke altid med Sikkerhed kan afgøre, allerede i September, om et Individ opnaar Modenhed i den forestaende Yngleperiode eller ej, tyder Undersøgelserne i September 1922, i hvilke alle undersøgte Individer blev skønnet umodne, ubetinget paa, at Modenheden nu indtræder ved en højere Alder end i 1910.

#### D. Undersøgelser af Markedsrødspætter i landbragte i Esbjerg.

I Tiden fra 23de September til 10de November 1922 blev der maalt 247 Prøver af Markedsrødspætter, landede i Esbjerg, og Maalingerne er meddelt i "Table of Measurements B". Over Halvdelen af Prøverne stammer fra Fangster, som er gjort i Feltet  $B_4$ , og tilmed fra den Del af  $B_4$ , som ligger nord for Horns Rev, og som vi har benævnt  $B_c$ . Disse Prøver bestaar gennemsnitlig af 110 Individer hver, medens Prøver fra  $C_2$ ,  $B_1$  og  $D_2$ , hvor Rødspætterne er større, kun bestaar af 30—40 Individer. Ialt er der maalt 23299 Rødspætter. For Salg i Danmark er Mindstemalet 25.7, for Eksport er det om Sommeren indtil Oktober 22.5 cm og derefter 24.0 cm.

##### a. Længernes Hyppighedsfordeling i Felterne $B_4$ og $B_5$ .

En Sammenligning af Længdefordelingen pr. 1000 Rødspætter fra  $B_4$  fanget i Efteraaret 1922 (Table 15) med Maalinger fra Efteraarene 1905<sup>1</sup> og 1919<sup>2</sup> viser klart, at Prøverne fra 1922 indeholder forholdsvis mange flere smaa Rødspætter end de andre Prøver. Af Table 16 ses det, at den relative Hyppighed af Rødspætter under 27 cm's Længde er henimod dobbelt saa stor i 1922 som i 1919, og mere end dobbelt saa stor som i 1904—1905, skønt Fiskeriet i 1922 væsentlig foregik paa dybere Vand og udelukkende nord for Horns Rev. For at udelukke Virkningen af en mulig forskellig Sortering har vi desuden sammenlignet Rødspætter over 27 cm særskilt. Table 17 giver for  $B_4$  og  $B_5$  Fordelingen af 1000 Rødspætter over 27 cm blandt tre Størrelsesgrupper.

Man vil se af denne Tabel, at Prøverne fra  $B_4$  og  $B_5$  taget i 1922 viser omtrent samme Hyppighedsfordeling, og at denne ikke afviger væsentlig fra Hyppighedsfordelingen for  $B_5$  i 1904—1905. Derimod indeholder Prøverne fra  $B_4$  taget i 1904—1905 og 1919 et betydeligt større Procenttal Rødspætter over 30 cm end de øvrige Prøver.

Det er tidligere paavist, at der i September 1905 i landbragtes ganske usædvanlige Fangster fra Omraadet  $B_4$ , som i Sammenligning med de øvrige Fangster paa den Tid og fra det Omraade bestod af ualmindelig store Rødspætter. Blandt de 24 Prøver benyttede i Table 17 stammer 8 fra saadanne Fangster. De øvrige 16 Prøver giver følgende Procenttal:

Under 30 cm .....	69.4 %
mellem 30 og 33 cm .....	22.1 %
over 33 cm .....	8.5 %

som hvert ligger imellem de tilsvarende Værdier for 1919 og 1922.

Vi kommer saaledes til følgende Resultater: Maalingerne af Markedsrødspætter fra  $B_4$  viser, at Procenttallet af Rødspætter over 30 cm i Bestanden af Rødspætter over 27 cm maa være betydelig mindre i Oktober 1922 end i August og September 1919 og tillige mindre end i Sept.—Nov. af Aarene 1904—1905. Maalingerne fra  $B_5$  viser ogsaa et større Procenttal af Rødspætter mindre end 27 cm i 1922 end i 1904—1905, men dette kan skyldes forskellig Sortering; man finder nemlig for Rødspætter over 27 cm væsentlig den samme Størrelsesfordeling i de to Maaleperioder.

##### b. Længernes Hyppighedsfordeling i Omraaderne $C_2$ , $B_1$ og $D_2$ .

Prøverne fra Omraaderne  $B_1$  og  $D_2$  er slet ikke og Prøverne fra  $C_2$  næsten ikke paavirkede af Sortering, saa at de direkte kan sammenlignes med Prøver fra tidligere Aar.

Et Gennemsyn af de enkelte Prøver fra  $C_2$  i "Table of Measurements B" viser, at Gennemsnitslængderne i 1922 er meget forskellige, eftersom Fangsterne hidrører fra  $L_9$ ,  $K_9$  og  $K_{10}$ , d. v. s. fra Omraadet øst for Dogger Banken, som vi skal benævne  $C_2 e$ , eller de hidrører fra  $G_{10}$ ,  $H_{10}$ ,  $K_{11}$  og  $K_{12}$ , d. v. s. Om-

<sup>1</sup> Se A. C. JOHANSEN 1910, p. 41.

<sup>2</sup> Se K. SMITH 1921, p. 20.

raadet nordvest og nord for den nordøstlige Spids af Banken, som vi benævner  $C_2$  n. w. I det sidstnævnte Omraade er Rødspætterne gennemsnitlig meget større end i det førstnævnte og tillige større end i den mellemliggende Del af Dogger Banken. (Se Table 18 og 19). Tidligere danske Maalinger fra  $C_2$  foretaget i 1916 og 1919 omfatter kun Prøver fra  $C_2$ , hvorfor vi i Table 18 behandler Prøverne fra de to Omraader hver for sig. Tabellen viser, at den store relative Hyppighed af Rødspætter over 35—40 cm, som forefandtes i 1919 — sammenlignet med 1916 — er ganske forsvundet fra  $C_2$  i 1922, da de mindre Rødspætter derimod er relativt hyppigere end i 1916.

Af Table 19, hvor Gennemsnitslængden er beregnet af de enkelte Prøvers Gennemsnitslængder ved at give hver af dem samme Vægt, og hvor den empiriske Middelafvigelse er angivet, ser man, at Afgigelserne mellem Gennemsnitslængderne i 1922 og i 1916 og 1919 er flere Gange saa store som Afgigelsernes Middelfejl. Derimod er Gennemsnitslængden for  $B_1$  og  $C_2$ , n. w. i 1922 væsentlig større, end den var for  $C_2$  i 1919. Det kan derfor tænkes, at den iagttagne Formindskelse af Gennemsnitslængden af Rødspætter i  $C_2$  til Dels skyldes en forskellig regional Fordeling af Rødspætterne i 1922 og i Aarene 1919 og 1916.

#### c. Længdernes Hyppighedsfordeling i Feltet $A_3$ .

Prøverne fra  $A_3$  indeholder 783 % Rødspætter under 27 cm, medens Prøver fra Efteraarene 1904—1905 og 1919 kun indeholdt omtrent halvt saa mange per mille. Naar man, for at borteliminere Mindstemalets Indflydelse alene sammenligner Rødspætter over 27 cm, finder man, at ogsaa blandt disse er de mindste Længdegrupper afgjort relativt hyppigere repræsenterede i 1922 end i 1919. Mellem 1922 og 1904—1905 er der ogsaa en dog mindre fremtrædende Forskel i samme Retning. Baade i 1919 og i 1904—1905 udgør den Del af Rødspætterne over 27 cm, som er større end 30 cm, en meget større Procentdel end i 1922.

Baade for  $B_4$  og  $A_3$  har vi altsaa ved at sammenligne Rødspætter over 27 cm, hvis Hyppighedsfordeling kan anses for uafhængig af de vekslende Mindstemaal, fundet, at Størrelsesgruppen over 30 cm i 1922 udgør en meget mindre Procentdel end i 1919 og en noget mindre Procentdel end i 1904—1905. Naar det forholder sig saaledes, er det sandsynligt, at den store relative Hyppighed af Rødspætter under 27 cm, som er iagttaget i 1922, ikke alene skyldes et mindre Mindstemaal, men maa opfattes som et Tegn paa en større relativ Hyppighed af denne Størrelsesgruppe i de usorterede Fangster.

#### d. Markedsrødspætternes Alder i Feltet $B_c$ i Efteraaret 1922.

Ved Hjælp af Fiskeforsøgene i September 1922 har vi gjort et Førsøg paa at opstille Alders- og Længdefordelingen for Markedsrødspætter fra  $B_c$  i Efteraaret 1922. Idet vi tog vort Udgangspunkt fra Summen af Rødspætter fangede pr. Time ved hver af Stationerne i  $B_c$ , antog vi, at Rødspætter over 27 cm ikke berøres af Sorteringen, og at Hyppighederne for Størrelsesgrupper under 27 cm ved Sorteringen reduceres saaledes, at hver Længdegruppe kommer til at udgøre den samme Procentdel af samtlige Rødspætter over 27 cm som blandt Markedsrødspætterne fra  $B_4$  (Table 15). Ved denne Beregningsmaade er vi naaet til Table 21. Det ses af denne Tabel, at 53 % af Markedsrødspætterne hører til III-Gruppen, 22 % til II-Gruppen, 21 % til IV-Gruppen og de øvrige 4 % til V-Gruppen, Naar Markedsrødspætterne er saa unge, er det klart, at deres Gennemsnitslængde og overhovedet deres Længdefordeling i høj Grad afhænger af Væksthastigheden i de to sidste Vækstperioder.

Fra Foraaret 1922 foreligger der en Prøve af Markedsrødspætter (Table 22) fra den dybere Del af Feltet  $B_a$ , som er otolithundersøgt. Omtrent Halvdelen af disse Rødspætter er fire Aar gamle, omtrent en Femtedel tre Aar gamle og ligesaa mange fem Aar gamle. De har gennemsnitlig oplevet 4.2 Vækstperioder og er saaledes af omtrent samme Gennemsnitsalder som Markedsrødspætter fra  $B_a$  og  $B_b$  i Efteraaret 1922, der ifølge Table 23 den 1ste April henholdsvis havde Gennemsnitsalderen 3.8 og 3.6.

Naar man sammenligner Prøven fra Marts 1922 med Prøver af Markedsrødspætter fra  $A_a$  taget i Foraarene 1919 og 1920, finder man, at den er gennemsnitlig 1.1 Aar yngre end disse. I September 1922

er Markedsrødspætter fra  $B_a$  ifølge Table 23 kun 0.5 Aar yngre end Markedsrødspætter fra  $A_a$ , saa at vi har Grund til at antage, at Gennemsnitsalderen af Markedsrødspætterne i Horns Rev Omraadet er aftaget, efter at Fiskeriet har været drevet i mere normalt Omfang i Aarene efter Krigen.

Vi finder altsaa to Aarsager til, at Markedsrødspætterne fra  $B_4$  i 1922 er blevet mindre, end de var i 1919. For det første er den relative Hyppighed af de ældre Aldersgrupper aftaget blandt Markedsrødspætterne som Følge af, at Fiskeriet i Aarene efter Krigen igen er drevet med mere normal Intensitet. For det andet har Væksten i 1922 og sandsynligvis i 1921 været ualmindelig langsom, saa at Gennemsnitslængden af Markedsrødspætter fra hver Aldersgruppe i 1922 antagelig er mindre end i 1919. Den ringe Vækst forklarer tillige, at Markedsrødspætterne i 1922 var endnu mindre end i 1904—1905.

#### e. Markedsrødspætternes Tæthed i Efteraaret 1922.

For at danne os en Forestilling om Tætheden af Markedsrødspætterne i de forskellige Felter, med hvilke vi ved Bearbejdelsen af Fiskeforsøgene har arbejdet, har vi sammenlignet Antallet af Rødspætter længere end 24 cm indfangede ved disse Forsøg (se Table 23). Fra 1ste Oktober er det tilladt at islandbringe Rødspætter over 22.5 cm; men som det ses af Table 15, findes der dog kun faa af Længderne 22 og 23 i Prøverne. Heller ikke Rødspætter paa 24 cm er fuldt repræsenterede iblandt de islandbragte Rødspætter, men ved ganske at udelukke Rødspætter under 24 cm og ved at medregne alle Individer paa 24 cm fra Fiskeforsøgene, faar vi antagelig en rimelig Repræsentation for Markedsrødspætterne i Henseende til Alder og Tæthed. Vi finder saaledes den i Table 23 fremstillede Tætheds- og Aldersfordeling. Fordelingen mellem Aldersgrupper stemmer for  $B_c$ 's Vedkommende godt med den i Table 21 meddelte, som naaedes ad en mere omstændelig Vej.

Table 23 viser, at Markedsrødspætternes Tæthed i September var usædvanlig stor i  $B_c$  (d. v. s. den Del af  $B_4$ , som ligger nord for Horns Rev). Tætheden var her 3—4 Gange saa stor som i  $B_b$  og omtrent 10 Gange saa stor som i  $B_a$  og i C.

Fordelingen af de maalte Prøver af Markedsrødspætter mellem Felterne (se Table 15), som giver et tilnærmet Billede af den totale danske Fangsts Fordeling mellem Felterne, viser, at denne relativt rige Mængde af Markedsrødspætter i  $B_c$  ogsaa forefandtes i Oktobermaaned.

En Sammenligning mellem Table 23 og Table 1 godtgør, at den større Hyppighed af Markedsrødspætter i  $B_c$  skyldes den hurtigere Vækst. Sammenligner man i Table 1 en Aldersgruppens Tæthed i de forskellige Felter, ser man, at den maksimale Tæthed ikke for nogen af Aldersgrupperne falder i Feltet  $B_c$ . Men Forholdet mellem Antallet af Markedsrødspætter af hver af Aldersgrupperne II—IV og det samlede Antal Rødspætter af en Aldersgruppe er meget større for  $B_c$  end for  $B_a$  og  $B_b$  og overgaas kun af de tilsvarende Forhold for C. III-Gruppen, som i Felterne  $B_a$ ,  $B_b$  og  $B_c$  danner Grundstammen af Markedsrødspætterne, er omtrent lige saa tæt repræsenteret i  $B_a$  og  $B_b$  som i  $B_c$ , men alligevel er Tætheden af Markedsrødspætter af III-Gruppen i  $B_a$  kun ca.  $\frac{1}{11}$  og i  $B_b$  kun ca.  $\frac{1}{4}$  af Tætheden i  $B_c$ . II-Gruppen, som i  $B_c$  bidrager væsentlig til Bestanden af Markedsrødspætter, er i  $A_a$  og  $B_a$  ganske uden Betydning for Fiskeriet, skønt dens Tæthed her er tre Gange saa stor som i  $B_c$ .

#### E. Sammenfattende Bemærkninger.

Paa Grundlag af Fiskeforsøgene i Horns Rev Omraadet, som blev foretaget paa »Dana«s Togt i September 1922, har vi kunnet danne os et Billede af Rødspættebestandens Sammensætning i Henseende til Alder og Køn, og af Tætheden og Gennemsnitslængden for de enkelte Aldersgrupper. Vi har fundet følgende karakteristiske Træk. I- og II-Grupperne optræder med usædvanlig Tæthed syd for Horns Rev indenfor 30-Meterkurven, især vest for Graadyb. Paa samme Sted er Gennemsnitslængden for hver af disse Aldersgrupper betydelig mindre end nord og syd derfor. Tætheden er for hver Aldersgruppe mindre i den nordlige Del af  $A_3$  end i den Del af Feltet, som ligger syd for Horns Rev. Udenfor 20-Meterkurven er Tætheden

for Aldersgrupper ældre end tre Aar omrent den samme nord og syd for Horns Rev, men den gennemsnitlige Længde for hver Aldersgruppe er betydelig større i det nordlige end i det sydlige Omraade. Væksten er i Virkeligheden saa forskellig, at naar man betragter Tæthedens af Markedsrødspætter, finder man, at denne er omrent fem Gange saa stor nord for Horns Rev i B<sub>c</sub> som syd for Revet i B<sub>a</sub> og B<sub>b</sub>, skønt den maksimale Tæthed for hver enkelt Aldersgruppe bestandig findes syd for Revet. I hele Undersøgelsesomraadet med Undtagelse af det Omraade, som ligger indenfor 20-Meterkurven og syd for Horns Rev, er III-Gruppen den fremherskende i Antal blandt Markedsrødspætterne, men ved Siden af den udgør IV-Gruppen en ganske anselig Del af Markedsfisken, medens II-Gruppen kun er af nogen Betyning som Markedsfisk nord for Horns Rev og i det sydlige Omraade udenfor 30-Meterkurven. Syd for Revet og indenfor 30-Meterkurven, hvor II-Gruppen er særlig tæt, har Væksten været saa langsom, at Mindstemalet endnu ikke er naaet.

En Undersøgelse af de to Køns relative Hyppighed i hver Aldersgruppe har vist, at Hunnerne er relativt hyppigere nær ved Kysten end længere ude, og tillige, at for hvert af de undersøgte Felter tiltager Hunnernes relative Hyppighed med voksende Alder. Betragter man under eet alle Rødspætter ældre end et Aar iagttagtes der ogsaa en Aftagen i Hunnernes relative Hyppighed fra Kysten udefter. Summen for alle Stationer af Individer af en Aldersgruppe fanget pr. Time viser en lille Tilvækst i Hunnernes relative Hyppighed med Alderen, og dette kan forklares ved, at et Overskud af de ældste Hanner sandsynligvis er vandret ud af Undersøgelsesomraadet, siden de er i saa fremherskende Flertal ved de vestligste Stationer. Den talmæssige Fordeling af Hanner og Hunner forklares ved at antage, at Hanner har en større Tilbøjelighed end Hunner af samme Alder til at vandre ud fra Kystgrundene. De undersøgte Rødspætter blev alle anset for at være umodne, og den fundne talmæssige Fordeling kan ikke alene forklares ved, at modne Hanner muligvis allerede er vandret ud af Undersøgelsesomraadet. Den fra Kysten og udefter stigende relative Hyppighed af Hanner iagttagtes nemlig allerede tydelig for II-Gruppen, som ganske sikkert ikke indeholder modne Individer, og som næppe spreder sig vestpaa udover det undersøgte Omraade. Paa hver enkelt Station er Gennemsnitslængden for Hunner i Reglen ganske lidt større end for Hanner af samme Aldersgruppe. Men sammenligner man under eet alle Hunner og Hanner af en Aldersgruppe fra Omraadet syd for Horns Rev eller nord for Revet forsvinder denne Forskel, og vi er derfor tilbøjelige til at tro, at Væksten i de unge Aar er den samme for Hanner som for Hunner, og at den Forskel i Gennemsnitslængde, som iagttagtes paa adskillige Stationer, er fremkaldt ved, at de større Hanner er udvandret i større Antal end Hunner af samme Længde.

En Sammenligning med Fiskeforsøg fra Efteraarene 1903—1905 viser, at Tæthedens for I- og II-Gruppen i Omraadet vest for Graadyb og indenfor 30-Meterkurven var mindst tre Gange saa stor i September 1922 som i de tidlige Aar, og Fiskeforsøgene fra Foraaret 1907 tyder ogsaa paa en meget ringere Tæthed end i 1922. Fra tidlige Aar er der kun faa Iagttagelser fra Omraadet nord for Horns Rev, men de synes at antyde, at Tæthedens i 1922 er relativt stor udenfor 20-Meterkurven og lille indenfor denne Kurve. Med Hensyn til Væksten tyder de ret sparsomme Maalinger af aldersanalyserede Prøver fra Efteraaret 1905 paa, at Gennemsnitslængderne for II—IV-Grupperne i Omraadet vest for Graadyb indenfor 30-Meterkurven i 1905 var 4—6 cm længere end i 1922. Gennemsnitslængderne for de samme Aldersgrupper var i Feltet C kun et Par Centimeter større end i 1922, saa at vi kan antage, at det er Væksthastigheden i Felterne A<sub>a</sub> og B<sub>a</sub>, som i 1922 var saa tæt befolkede med Rødspætter, der særlig har forandret sig. En Sammenligning med Undersøgelserne i Foraaret 1907 viser, at Gennemsnitslængden af II-Gruppen nord for Horns Rev i 1922 staar mindre tilbage for Gennemsnitslængden fra den tidlige Periode, end Tilfældet er for II-Gruppen syd for Horns Rev, hvilket bestyrker Formodningen om, at der er en Aarsagssammenhæng mellem den ringe Vækst og den store Tæthed af I- og II-Gruppen vest for Graadyb.

En Sammenligning af Gennemsnitslængderne for de forskellige Aldersgrupper i Forbindelse med Resultaterne af Mærkningsforsøgene fra 1920 fører os til den Slutning, at de smaa Gennemsnitslængder, som vi har fundet for Aldersgrupperne i September 1922 især skyldes en langsom Vækst i 1922 og maaske i 1921.

Materialet fra 1903, 1905 og 1907 bekræfter den Iagttagelse, at Hunnernes relative Hyppighed aftager fra Kystomraadet udefter. Iagttagelserne fra 1903 og 1905 synes at tyde paa, at Hunnernes relative Hyppighed i 1922 er mindre end i disse Aar, hvad der maaske hænger sammen med en senere Indtræden af Modenheden og en deraf følgende senere delvis Udskillelse af Hanner fra Hunner.

Maalingerne af Markedsrødspætter fra B<sub>4</sub> (alle fra B<sub>c</sub>) og A<sub>3</sub> viser, at Hyppigheden af Rødspætter over 30 cm's Længde er aftaget stærkt siden 1919, baade taget i Forhold til Antallet af Rødspætter over 27 cm og til Totalantallet af Markedsrødspætter. Prøverne fra den Del af C<sub>2</sub>, som ligger sydøst for den nordøstlige Ende af Dogger Banken viser ogsaa en aftagende Længde fra 1919 til 1922, da Gennemsnitslængden af Rødspætterne endogsaa er mindre end i 1916. Der kan ikke være Twivl om, at dette væsentlig skyldes Krigstidens Fredning og det paafølgende mere intensive Fiskeri, som har bevirket, at Gennemsnitsalderen af Markedsrødspætterne var særlig høj i 1919. For de Dele af A<sub>3</sub> og B<sub>4</sub>, som ligger syd for Horns Rev peger de aldersanalyserede Markedsprøver i Retning af en formindsket Gennemsnitsalder for Markedsrødspætter fra 1919—1920 til 1922. Hvad B<sub>4</sub> og A<sub>3</sub> angaaer, finder vi desuden i den usædvanlig langsomme Vækst i Sommeren 1922 og maaske i 1921 en Aarsag, som maa virke til at formindske Antallet af Rødspætter over 30 cm. i Forhold til det samlede Antal Rødspætter over 27 cm. Ogsaa i Sammenligning med Markedsprøver fra Aarene 1904—1905 er Prøverne fra B<sub>4</sub> og A<sub>3</sub> taget i Efteraaret 1922 underlelse i Henseende til Længde, og dette maa rimeligvis forklares ved den langsomme Vækst i Aarene 1921—1922.

### III. Mærkningsforsøg i Foraarene 1920 og 1921.

#### a. De mærkede Rødspætters Vandringer.

Den 23de April 1920 udsattes ialt 300 mærkede Rødspætter paa fire forskellige Steder (Dybde: 4—12 m) i Nærheden af Graadyb (se Fig. 7 og 8). Inden Udløbet af Majmaaned genfangedes 16 af disse Rødspætter i A<sub>3</sub> paa væsentlig større Dybder end Udsættelsesstedernes. I Junimaaned genfangedes 69, hvoraf de 66 i A<sub>3</sub> sydvest for Udsættelsesstederne. I August og September ligger Genfangststederne for en Del længere ude end A<sub>3</sub>, men i Slutningen af Vinteren og i det følgende Foraar sker Genfangsterne igen væsentlig i A<sub>3</sub> syd for Horns Rev. Forsøgene bekræfter altsaa de tidlige Erfaringer om en Vandring bort fra Kysten om Sommeren og en senere delvis Tilbagevenden til Kystomraadet.

Den 27de og 28de Maj 1920 udsattes ialt 200 mærkede Rødspætter paa to Steder (Dybde: 15 og 15.5 m) syd for Horns Rev (se Fig. 8 og 9). Inden Udløbet af Junimaaned genfangedes 66 af disse Rødspætter gennemgaaende paa lidt større Dybde end Udsættelsesstederne. I Augustmaaned indfangedes yderligere 7 Individer paa endnu lidt dybere Vand, og derefter fangedes kun endnu 6 Rødspætter. Disse to Forsøg tyder paa, at Vandringen bort fra Kysten er mindre udpræget fra disse Grunde af Dybde 15—16 m end fra Graadyb. Af Fig. 10, som viser de længere Vandringer fra de 6 omtalte Forsøg, synes det at fremgaa, at Rødspætterne, som i Foraaret 1920 blev udsat syd for Horns Rev, har vist større Tilbøjelighed til at vandre vestpaa og sydpaa end nordpaa over Revet.

Den 24de April 1921 udsattes ialt 350 mærkede Rødspætter paa tre Steder (Dybde: 4—10 m) vest for Fanø. (Se Fig. 11—13). Allerede inden Udgangen af Aprilmaaned genfangedes 50 Individer og i Majmaaned yderligere 110. Genfangsterne fandt især Sted sydvest for Graadyb, lidt vestligere end Udsættelsesstederne. I Junimaaned indfanges 8, og i Juli igen 8 Rødspætter; for de sidste laa Genfangststederne kendelig længere ude fra Kysten end i Majmaaned. Derefter fangedes kun endnu 2 Eksemplarer. Ogsaa disse Forsøg viser en tydelig Vandring bort fra Kysten om Sommeren.

#### b) Genfangstprocenten for mærkede Rødspætter.

Af de 850 Rødspætter, som udsattes i Mærkningsforsøgene i Foraarene 1920 og 1921 genfangedes ialt 46 % (Table 25), og 44 % indfangedes inden Udgangen af det første Aar efter Udsættelsen. Ved Mærkningsforsøgene i Foraarene 1906—1912 genfangedes 53 % i Løbet af et Aar, men Genfangstprocenten er

større jo tidligere paa Aaret Forsøgene udføres, og i de af Forsøgene, som foretages efter 14de April, er Genfangstprocenten i det første Aar efter Udsættelsen kun 46. Der synes altsaa ikke at være sket nogen væsentlig Forandring i Fiskeriets Intensitet.

Tallene i Table 25 antyder svagt, at Genfangstprocenten er større for Markedsrødspætter end for Undermaalsfisk, endvidere at for Rødspætter af samme Størrelsesgruppe er Genfangstprocenten for Hunner lidt større end for Hanner, og at følgelig Genfangstprocenten i det store og hele er større for Hunner end for Hanner, siden de udsatte Hunner gennemsnitlig er længere end Hannerne (se Table 24).

### c) De mærkede Rødspætters Vækst.

I Mærkningsforsøgene fra April og Maj 1920 har man observeret den paa Fig. 14 indtegnede Gennemsnitstilvækst af Længden, som ogsaa for Majforsøgene ved en Korrektion er regnet ud fra Længden den 23de April, da de første fire Forsøg begyndtes. Den udjævnede Kurve viser, at den gennemsnitlige aarlige Vækst fra 1ste April 1920 til 1ste April 1921 er omtrent 7 cm. Man ser, at den observerede gennemsnitlige Tilvækst er betydelig større for September og Oktober end for Maanederne November til Marts incl., hvoraf følger, at den ved Udjævningen bestemte gennemsnitlige aarlige Vækst maa være behæftet med en ret betydelig Usikkerhed. For at danne os en Forestilling om denne, har vi sammenlignet den observerede Tilvækst i Længde for de 30 Individer, som er genfangede fra September 1920 til Maj 1921 incl. Deres gennemsnitlige Tilvækst er 6.1 med Middelfejl 0.6. Da der maa antages at have været en kendelig Vækst i Sept.—Okt. og i April—Maj, og da dette maa bidrage til at forøge Middelfejlen, kan man maaske vente, at Middelfejlen for den aarlige Vækst ikke overstiger 0.6.

De tidligere Bestemmelser af den aarlige Vækst ved Hjælp af Mærkningsforsøg i Horns Rev Omlædet er mindst lige saa usikre. Men da Væksten for Aarene 1908—1912 kun var henholdsvis 5.3, 3.1, 4.6, 4.5 og 3.5 cm eller i Gennemsnit 4.2 cm, kan der næppe være Twivl om, at Væksten i disse Aar var langsmmere end i 1920. For Aarene 1905—1907 fandt man derimod en aarlig Vækst af henholdsvis 7.9, 6.1 og 7.7 cm, hvilket er tilnærmelsesvis den samme som i 1920.

I Mærkningsforsøgene fra 1921 blev alle de genfangede Rødspætter indfangede inden Afslutningen af den første Vækstperiode og 92 % af dem i Løbet af de to første Maaneder efter Udsættelsen, saa at de kun giver ringe Oplysning om Væksten. De i Juni og Juli genfangede Eksemplarer lader formode, at Væksten var langsmmere i 1921 end i 1920.

# MEDDELELSE FRA KOMMISSIONEN FOR HAVUNDERSØGELSER
